Abstract

Pancreatic regeneration after pancreatectomy has been well documented in animal models. However, the phenomenon of pancreatic regeneration in diabetes has not been exploited as yet. We report here the restoration of euglycaemic status in streptozotocin (STZ)-induced diabetic BALB/c mice, after 50% pancreatectomy. We observed that, after pancreatectomy, STZ-diabetic mice showed a rapid improvement in glycaemic status, starting from the 8th postoperative day, and remained normoglycaemic throughout a 90-day follow-up study. STZ-induced diabetic and control non-diabetic BALB/c mice underwent pancreatectomy and were monitored regularly for changes in body weight, plasma glucose and serum insulin concentrations and histological status of the pancreas. All the pancreatectomised animals showed euglycaemic status from about 20 days after operation, whereas a majority (around 70%) of the diabetic, sham-

operated animals died of sustained hyperglycaemia by 20–30 days after operation. Examination of the regenerating pancreas indicated nesidioblastotic activity and supported the theory of a ductal origin of islet stem cells. Islets isolated from the regenerating pancreas showed a progressive increase in islet area ($1227.9 \pm 173.2 \mu\text{m}^2$ on day 5 compared with $2473.8 \pm 242.0 \mu\text{m}^2$ by day 20). The increment in insulin concentrations and subsequent decrement in glycaemia of the diabetic pancreatectomised animals indicate islet neogenesis occurring after the operative insult, leading to a normoglycaemic status, probably recapitulating ontogeny. We have shown that induction of a regenerative stimulus (pancreatectomy) in conditions of STZ-induced diabetes may trigger pancreatic regenerative processes, thereby restoring a functional pancreas, in STZ-diabetic mice.

Journal of Endocrinology (1999) **162**, 189–195

Introduction

Endocrine and exocrine pancreatic regeneration after pancreatectomy has been well documented in animal models (Bonner-Weir *et al.* 1993, Slack 1995), but pancreatic regeneration in diabetes has not been reported as yet. It is generally believed that the number of functionally intact β -cells in the islet organ is of decisive importance in the development, course and outcome of diabetes mellitus and also, possibly, for its reversal. A major complement of the β -cells in adults is established much earlier, during the neonatal period, when islet cells differentiate from primitive duct-like cells. The adult pancreatic β -cells are thus of a terminal nature and only about 3% of the islet cells are capable of proliferation (Swenne 1983, Tanigawa *et al.* 1997). However, the factors controlling such nesidioblastotic/proliferative events remain largely unknown. It is therefore important to identify those factors that determine pancreatic β -cell proliferation and nesidioblastosis. Nesidioblastosis, or neogenesis of islets, in adult mammals has been debated for a long time and various sources of islet neogenesis have been proposed. Increase in

pancreatic β -cell mass may result from mitotic proliferation of pre-existing islet cells, or islets may bud off from the ductal system of the pancreas (Slack 1995), arise from transformation of the acini into new islets, or may even be derived from the centro-acinar cells (Jindal *et al.* 1995). There is strong evidence that islet stem cells may exist in the pancreatic duct (Hellerstrom 1984, Bonner-Weir *et al.* 1993) and that these ductal epithelial cells may be switched into a proliferative/regenerative phase leading to nesidioblastosis. In mammals, organs such as the liver and pancreas are well known to inherit a strong regenerative potential; however, the process of regeneration has to be preceded by an operative insult that involves removal of a part of the entire organ (Michalopoulos & DeFrances 1997). Pancreatectomy has already been established as a model of diabetes (Bonner-Weir *et al.* 1983), and substantial regeneration of both exocrine and endocrine pancreas after 90% pancreatectomy has been documented (Bonner-Weir *et al.* 1993). However, attention has not been focused on regeneration of the diabetic pancreas. We carried out this study in an effort to understand the pancreatic regenerative processes in the diabetic condition.

Materials and Methods

Animals

BALB/c mice were studied in four groups: control/non-diabetic sham-operated (CS), diabetic sham-operated (DS), control/non-diabetic pancreatectomised (CPx) and diabetic pancreatectomised (DPx). All animals were obtained from an inbred population of BALB/c mice at the animal house of National Centre for Cell Science, Pune, India. For the DPx and DS groups, 8-week-old BALB/c mice (either sex) were rendered diabetic by an i.p. injection of streptozotocin (STZ; Sigma Chemical Co., St Louis, USA) in a dose of 200 mg/kg body weight (Bonner-Weir *et al.* 1993). STZ was reconstituted in chilled sodium citrate buffer (pH 4.5) just before injection. STZ-diabetic animals showing frank diabetic status (fasting plasma glucose >200 mg/dl) for 2 weeks were taken for the study.

Operative procedure

Ten-week-old BALB/c mice of either sex were taken for the operative procedure. Animals were fasted overnight and anaesthetised by i.p. administration of sodium thiopentone (40 mg/kg body weight). Animals were operated on following the procedure of Bonner-Weir *et al.* (1983) with slight modifications: the entire splenic portion of the pancreas was removed, keeping the mesenteric pancreas intact. The incisions were sutured using absorbable 6-0 catgut sutures from Stericat Gutstrings, Delhi, India and autoclipper from Becton Dickinson (Mountain View, CA, USA). All animals (pancreatectomised and sham operated) received an i.p. injection of gentamycin (3 mg/kg body weight), ampicillin and cloxacillin (20 mg/kg body weight) and diclofenac sodium (0.5 mg/kg body weight), for 3 days starting from the operative day, in addition to topical ointments (soframycin). In the case of sham operations, animals were anaesthetised as above, an incision was made and pancreata were handled as in the Px groups. Animals were then sutured as described earlier, without removal of the pancreas.

Glucose and insulin estimations

Plasma glucose was estimated by a glucose oxidase method using an Analox GM7 auto-analyser (Analox Instruments, London, UK), with calibration standards from Sigma (Poole, Dorset, UK). Serum insulin concentrations were measured by radioimmunoassay kit (Diagnostic Products Corporation, Los Angeles, CA, USA), using purified rat insulin standard (Novo Nordisk, Denmark; obtained as a gift from Prof. Claude Remacle, Université Catholique de Louvain, Louvain-la-Neuve, Belgium). Pancreatic insulin content was measured in pancreata collected in pre-chilled

acid-ethanol (75% absolute ethanol, 1.5% 10 M HCl and distilled water to make up the volume), minced, sonicated and kept overnight at -20°C before the assay.

Amylase estimations

Circulating amylase concentrations were measured from serum samples collected at predetermined time points. Amylase was detected using a standard amylase detection kit from Beacon Diagnostics (Navsari, India).

Histological procedures

Pancreas from the pancreatectomised and sham-operated mice were taken from animals killed 15 days after the operative procedures, and fixed in 10% buffered formaldehyde. Sections 7 μm thick were taken on a rotary microtome (Reichert-Jung 2030 Biocut, Cambridge instruments GmbH, Heidelberg, Germany) and stained with haematoxylin and eosin (HE) and light-green.

Image quantification

In order to quantify the pancreatic islet size, we isolated islets from animals in the DPx group at 5 and 20 days after pancreatectomy, following the procedure of Gotoh *et al.* (1985). Islets isolated from non-diabetic, sham-operated animals of the same age were taken as controls. In order to avoid a selection bias in islet size, pancreata from control and Px groups were processed for islet isolation in a single batch of experiments and islet isolation was carried out under perfectly identical conditions. Islets were suspended in RPMI 1640 medium with 10% FCS, handpicked, counted and then taken for quantification. Computations were done on a Kontron image analysis system (Kontron Elektronik GmbH, München, Germany) connected to a Ziess microscope. Islets were observed, images captured with a Variocam, Germany PCO CCD imaging camera and quantifications of islet size were made using the Kontron Image analysis software version 2.04.

Statistical analysis

Computations were performed using Jandel Scientific Sigma-stat statistical package (version 4 for Windows 95). Results are expressed as means $\pm$ s.e.m. for normally distributed data or median and interquartile range when data were not normally distributed. Differences between groups were tested by Mann-Whitney test and serial changes in plasma glucose and serum insulin concentrations by paired *t*-test or Wilcoxon test as appropriate.

Results

The CS group (Fig. 1) showed an increase in body weight (22.3 ± 0.3 to 24.6 ± 0.5 g) during the period of study.

Figure 1 Body weight profiles throughout the period of study in the CS ($n=10$), CPx ($n=10$), DS ($n=9$) and DPx ($n=15$) animal groups. Data are expressed as means $\pm$ S.E.M.

CPx animals showed a rapid decrease in body weight during the first 8 days after operation (25.1 ± 0.8 to 21.3 ± 0.7 g) and then showed a steady weight gain later on (21.3 ± 0.7 to 23.6 ± 0.5 g). The DPx group showed a similar trend, except that the initial decline in body weight (21.8 ± 0.5 to 19.4 ± 0.7 g) was followed by a much more rapid weight gain (19.4 ± 0.7 to 22.7 ± 0.4 g) later on (Fig. 1).

The DS group animals had a fasting plasma glucose concentration of 309 ± 6.1 mg/dl on the day of operation, and maintained hyperglycaemic levels on day 5 (336 ± 12.6 mg/dl), day 10 (331 ± 14.2 mg/dl), day 15 (326 ± 25.1 mg/dl) and day 20 (290 ± 37.7 mg/dl) after the day of operation. In the DS group, only three of nine animals survived the glycaemic stress after 20 days of uncontrolled diabetic status. However, these survivors remained diabetic throughout the period of study (fasting plasma glucose 273 ± 12.8 mg/dl). The CS group animals remained euglycaemic (97.0 ± 5.7 to 109.3 ± 8.1 mg/dl) throughout the period of study. The CPx group animals showed an initial increase in plasma glucose (91.1 ± 6.6 to 263.8 ± 13.2 mg/dl) that peaked at the 4th postoperative day (Fig. 2) and reduced to normal values around the 20th postoperative day. After pancreatectomy, animals in the DPx group similarly showed an initial increase in plasma glucose (280.8 ± 10.9 to 326.1 ± 14.7 mg/dl) that peaked on the 4th postoperative day and stabilised to near-normal values about 15 days after operation (183.1 ± 8.6 mg/dl). All the animals that were rated as frank diabetic at one time or other were also seen to be positive for glucose

Figure 2 Plasma glucose (mg/dl) and serum insulin (μ U/ml) concentrations in the CPx and DPx animal groups. Data are expressed as means $\pm$ S.E.M. Day 0 represents the day of operation. Postoperative serum insulin values, from 6 h (0.25 days) after pancreatectomy, are from seven animals in each group.

in the urine, whereas the DS group animals had an appreciable amount of ketone in the urine (data not shown).

Serum insulin concentrations in the DPx group were negligible (0.9 ± 0.3 μ U/ml) 6 h after pancreatectomy, increasing to suboptimal values on day 3 (9.5 ± 1.4 μ U/ml) and stabilising to normal levels on day 30 (12.1 ± 0.7 μ U/ml) (Fig. 2). In contrast to this, the serum insulin concentrations of CPx group animals were distinctly higher (7.9 ± 0.3 μ U/ml) than those of DPx animals, 6 h after pancreatectomy, decreasing at 18 h (5.9 ± 0.7 μ U/ml) and stabilising again by day 30 (13.2 ± 2.0 μ U/ml). The 6-h postoperative serum amylase concentrations in CPx (50.2 ± 2.3 U/dl) and DPx (42.4 ± 1.3 U/dl) animals increased rapidly, reaching control values by 24 h after operation in the CPx (58.4 ± 0.3 U/dl) and the DPx (56.1 ± 0.3 U/dl) groups. Amylase concentrations in these groups varied significantly compared with those in the CS group at 6 h (58.0 ± 0.4 U/dl; $P < 0.05$), with no significant differences at 24 h after operation (59.1 ± 0.6 U/dl).

The pancreatic insulin content was also estimated from a limited number of animals, killed at predefined time points. The regenerating pancreas showed an increasing insulin content from day 5 in both the DPx (0.8 ± 0.1 U/g) and the CPx (2.6 ± 0.5 U/g; $P = 0.02$) groups, reaching control values by day 30 (4.6 ± 0.2 U/g in group DPx, 4.9 ± 0.1 U/g in group CPx), compared with the insulin content of the CS group (5.1 ± 0.2 U/g) on the 30th postoperative day.

Figure 3 Pancreas from BALB/c mice of: (a) CS group, HE stained and (b) DS group, HE stained. (c) Islets from DPx animal 15 days after the operative procedure; sections stained with HE and light-green. Note the budding of endocrine cells (arrows) from a small, terminal pancreatic ductule ($\times 360$). (d) An islet isolated from regenerated pancreas of DPx animals, stained with Dithizone (Sigma, Poole, Dorset, UK).

The pancreatic sections of DPx and CPx animals showed neo-islets budding from the pancreatic duct (Fig. 3). Islets from the CS animals were larger than neo-islets from pancreatectomised animals, but showed no connections with the ductal system (Fig. 3). Islets isolated from regenerating pancreas of initially diabetic animals showed a progressive and significant increase in size and number between days 5 ($1227.9 \pm 173.2 \mu\text{m}^2$, 135.3 ± 8.5 islets/pancreas) and 20 ($2473.8 \pm 242.0 \mu\text{m}^2$, 592.0 ± 28.1 islets/pancreas; $P < 0.0001$ and $P < 0.05$ respectively) after pancreatectomy. However, they remained smaller in size than those isolated from CS animals 20 days after sham operation ($9257.2 \pm 1198.8 \mu\text{m}^2$; $P < 0.0001$). Islets isolated from the DPx animals on day 20 did not show any significant differences in islet number from those isolated from the CS group animals (592.0 ± 28.1 compared with 677.0 ± 34.9 islets/pancreas). Islet size of CPx group

animals at 5 and 20 days was not significantly different from that of the DPx group animals.

Discussion

In the present study, we demonstrated that subtotal pancreatectomy in STZ-diabetic mice induced pancreatic nesidioblastosis leading to restoration of normoglycaemic conditions. All the diabetic-pancreatectomised (DPx) mice exhibited reversal of their diabetic state, in contrast to continued diabetes and even death that was observed in the DS group animals.

The first sign of the diabetic status was the characteristic decrease in body weight in the STZ-induced diabetic (DS and DPx) and CPx animal groups. This decline was, however, of a transitory nature in the Px groups and of a

more permanent nature in the DS group, indicating their inability to compensate for the weight loss. In our mouse model, minimal body weights were obtained around the 8th postoperative day, followed by a subsequent progressive weight gain later on throughout the period of study. Concomitantly, during this time, the plasma glucose concentrations were also seen to decline towards normoglycaemic values. Immediately after pancreatectomy, a sharp peak indicating an increase in plasma glucose was detected in both the CPx and the DPx groups; however, the CPx group always maintained a comparatively lower, although diabetic, glucose concentration (263.8 ± 13.2 mg/dl) compared with that of the DPx group (326.1 ± 14.6 mg/dl).

These differences could be explained on the basis of the animal models that we used. In rats and mice, the pancreas is diffuse, not well defined as in primates (Scow 1957). These diffuse pancreata are termed mesenteric pancreas, in contrast to the well-defined splenic pancreas. In the 90% pancreatectomy model of Bonner-Weir *et al.* (1983), a sufficient β -cell mass is kept intact to trigger the regenerative process. However, in our diabetic pancreatectomy model, in which injection of STZ preceded pancreatectomy, there was scarcely any residual β -cell mass left to be triggered, even in the mesenteric pancreas. Hence it is logical to conclude that surgical removal of pancreas in the DPx model triggers only the ductal stem cell population to undergo neogenesis of islets, probably recapitulating ontogeny (Bonner-Weir *et al.* 1993). The differences in peaking of plasma glucose in the CPx and DPx groups may therefore be attributed to a normal/functional mesenteric pancreas in the CPx animals, which did not encounter any diabetogenic insult from STZ as occurred in the DPx or DS groups.

To investigate further the normalisation of blood glucose and body weight, we estimated the serum insulin concentrations, starting at 6 h after pancreatectomy. Insulin concentrations in the serum were negligible (0.9 ± 0.3 μ U/ml) in the DPx group at 6 h, but slowly increased to stable levels by the 30th day after operation, reflecting the regenerative activity of the endocrine pancreas. In contrast to this, the serum insulin profile (Fig. 2) of the CPx animals was distinctly different ($P < 0.05$) for the first 18 h after operation, although the differences in serum insulin concentrations were not statistically significant beyond 18 h after pancreatectomy. The initial serum insulin content in the CPx group might reflect release by mesenteric β -cells as a result of compensatory hypertrophy in response to the sudden load on the mesenteric pancreas after pancreatectomy. The same analogy explains the low insulin concentrations in the DPx animals, in which the mesenteric β -cells had also been destroyed by the toxic effect of STZ. The serum insulin profile of the DPx animals thus indicates production of insulin exclusively by the regenerating pancreas. In case of the CPx group, there was a decline in serum insulin at 18 h after pancreatec-

tomy, which probably could be attributed to exhaustion of the mesenteric β -cells as a result of the productive overload after the operative insult. The initial increased serum insulin concentrations in the CPx group can also be ascribed to release of insulin from the mesenteric pancreas in response to a sudden loss of pancreatic β -cells after pancreatectomy, whereas the insulin concentrations after the 3rd day might be reflecting insulin derived from the regenerating pancreas. However, this requires further investigation.

We also observed an increase in insulin content of the CPx and DPx pancreata compared with that of the diabetic (DS) animal group. The progressive increase in both serum and pancreatic insulin concentrations of the DPx animals is a positive indicator of islet neogenesis as a part of the regenerative process occurring after the operative insult. Our histological data from the DPx mice (Fig. 3), 15 days after pancreatectomy, give evidence of nesidioblastic activity in the regenerating pancreas, supporting the theory of a ductal origin of islet stem cells (Rosenberg & Vinik 1992, Rosenberg 1995). It is worth noting, however, that the DS animals exhibited no change in diabetic status. The reversal of diabetes obtained in the present study is comparable to that obtained in the CPx group and thus is accounted for solely by pancreatectomy. During the regenerative process, a highly significant increase ($P < 0.0001$) in islet size was also noted, indicating islet cell replication, growth, or both. Our data thus indicate that, in STZ-diabetic animals, pancreatectomy leads to regeneration of the endocrine pancreas, leading to restoration of the euglycaemic state as reflected in circulating glucose and insulin concentrations, in addition to the histological appearance, size and numbers of islets.

In the case of drug-induced diabetes, there is a selective loss of β -cells, islets, or both. In the case of pancreatectomy, there is a loss of both the endocrine and the exocrine counterpart, and regeneration of the lost pancreas is seen only after such an event. The presence of islet stem cells in the pancreatic duct has been well documented (Rosenberg & Vinik 1992, Bonner-Weir *et al.* 1993, Rosenberg 1995). Our pancreatectomy procedure was based on the requirement to keep the ductal pancreas intact, to induce the stem cells to switch into a regenerative or proliferative phase, and our experimental data indeed demonstrated induction of the expected regenerative process. Our findings do not agree with those of Okamoto (1985) and Yonemura *et al.* (1984), whose pancreatectomised animals (like the CPx group in our study) exhibited glucosuria during their 3-month follow-up study after 90% pancreatectomy, but rather our data support the work of Bonner-Weir *et al.* (1993) and the hypothesis of a ductal origin of islet stem cells (Hellerstrom 1984, Rosenberg & Vinik 1992, Bonner-Weir *et al.* 1993). This stem cell population in the pancreatic duct has been extensively studied, but the factor(s) responsible

for directing stem cells towards pancreatic regeneration remain largely unknown. A vital clue to pancreatic regeneration came from the cellophane-wrap model of Rosenberg & Vinik (1992), wherein they isolated a soluble polypeptide, ilotropin, from the pancreata of duct-obstructed non-diabetic hamsters. This polypeptide was shown to 'cure' almost 60% of STZ-induced diabetic hamsters when administered i.p. for 6 weeks. Our pancreatectomy studies can therefore be looked upon as presenting a much stronger and highly specific stimulus (compared with duct obstruction) for triggering the regenerative process.

We have also examined the exocrine and endocrine function in terms of serum amylase and insulin respectively, starting from 6 h after pancreatectomy. Our data are in agreement with those of Brokenbrough *et al.* (1988), and reveal a strong discordance in the regeneration of exocrine and endocrine tissues, the endocrine growth lagging behind the exocrine development. This lag is very much to be expected, as the genes for regeneration of the endocrine pancreas are expressed largely in the exocrine and ductal pancreas, and not in the endocrine counterpart (Miyaura *et al.* 1991). The understanding of this very basic process of regeneration in diabetic animals may prove to be a highly potent alternative to the cure of diabetes, and may revolutionise the therapeutic approach to treating the condition. It has also been shown that implantation of a 50% excess by number of β -cells in normal rat produced an equivalent decrease in the islet β -cell mass of the recipient, and was followed by a proportional increase after removal of the implant (Miyaura *et al.* 1991). The regenerative response thus seems to be proportional to the amount of pancreas removed, as is seen in case of hepatectomy (Michalopoulos & DeFrances 1997). This clearly indicates that intrinsic factors present within the pancreas somehow 'sense' the islet mass and manage homeostasis of the β -cell mass in the normal healthy condition. However, although these factors are intrinsic, they can be modulated by extrinsic factors such as diet, pancreatectomy, etc. (Bhonde 1996). As genetic factors are essential, but not sufficient, to cause diabetes, much depends on environmental factors, and the question remains as to what happens to these factors in the diabetic state? Is the diabetic pancreas a 'storehouse' of inhibitory factors that prevent regeneration, and is that the reason for islet neogenesis after removal of diabetic pancreas? The answers to these and many more questions could conveniently be sought by using the diabetic-pancreatectomised mouse model that we are proposing. The model opens up new avenues and dimensions in the emerging field of regenerative biology (Stocum 1997) with reference to diabetic research by triggering the formation of new tissues from old, and by tilting the balance towards regeneration.

Acknowledgements

The authors wish to thank Professors Claude Remacle and Joseph J Hoet and Dr Brigitte Reussen, WHO Collaborating Centre for Developmental Biology of the Endocrine Pancreas, Université Catholique de Louvain, Louvain-la-Neuve, Belgium for their help, suggestions and critical comments in the initial preparation and revisions of this manuscript. We also wish to thank Dr C S Yajnik, Director, Diabetes Unit, KEM Hospital, Pune for laboratory facilities and helpful criticism, Dr M R Wani, NCCS Pune for his initial guidance in the operative procedures, and Dr G C Mishra, Director, NCCS Pune for providing support throughout the study period. The project was funded by a grant from NCCS, Poona, India and the entire work is a part of the PhD thesis of A A H.

Part of the paper was presented at the AIDSPIT Conference of the EASD at Innsbruck, Austria, January 1998, and an abstract was published in *Hormone Metabolic Research*, January 1998.
