Abstract

Tetrahydrogestrinone (THG) is a recently identified compound having the greatest impact in the world of sports. In order to obtain a highly accurate and sensitive assessment of the potential anabolic/androgenic activity of THG, we have used microarrays to identify its effect on the expression of practically all the 30 000 genes in the mouse genome and compared it with the effect of dihydrotestosterone (DHT), the most potent natural androgen. Quite remarkably, we found that 671 of the genes modulated by THG in the mouse muscle levator ani are modulated in a similar fashion by DHT, while in the gastrocnemius muscle and prostate, 95 and 939 genes

respectively, are modulated in common by the two steroids. On the other hand, THG is more potent than DHT in binding to the androgen receptor, while, under *in vivo* conditions, THG possesses 20% of the potency of DHT in stimulating prostate, seminal vesicle and levator ani muscle weight in the mouse. The present microarray data provide an extremely precise and unquestionable signature of the androgenic/anabolic activity of THG, an approach which should apply to the analysis of the activity of any anabolic steroid.

Journal of Endocrinology (2005) **184**, 427–433

Introduction

Identification of tetrahydrogestrinone (THG) by the US Anti-Doping Agency has created a wave of shock in the world of elite athletes, coaches and suppliers of performance-enhancing drugs (Knight 2003a), while causing great concerns at the level of the International Olympic Committee (IOC). Soon after development of the appropriate test, THG has been identified in a still growing list of Olympic medal winners and other prestigious athletes. In addition to its potential performance-enhancing properties prohibited by the IOC, there are medical safety concerns related to THG. In fact, being, like norbolethone (Catlin *et al.* 2002), a drug never marketed as a pharmaceutical, the *in vivo* biological and toxicological activities of THG are practically unknown, thus increasing the risks of its use in humans. Thus, we have taken advantage of the powerful technique of microarrays which can assess the changes of expression of practically all genes in the genome to analyze the *in vivo* alterations of the genomic profile in androgen-sensitive tissues of the mouse, a species where 99% of the genes have direct counterparts in the human (Waterston *et al.* 2002).

Materials and Methods

Animals

Eleven- to twelve-week-old male C57BL6 mice obtained from Harlan (Indianapolis, IN, USA) were allowed to acclimate for 2 weeks. The animals were housed individually in an environmentally controlled room (temperature: $22 \pm 3^\circ\text{C}$; humidity: $50 \pm 20\%$; 12-h light–12-h darkness cycles, lights on at 0715 h). The mice had free access to tap water and a certified rodent feed (Lab Diet 5002 (pellet), Ralston Purina, St. Louis, MO, USA). The experiment was conducted in an animal facility approved by the Canadian Council on Animal Care (CCAC) and the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC). The study was performed in accordance with the CCAC Guide for Care and Use of Experimental Animals and the Laval University Committee for Animal Experimentation.

Treatment

Animals weighing between 24.0 and 32.4 g (mean = 28.2 ± 0.1 g) were randomized according to body weight

and were assigned to 19 groups of 10 animals each. On day 1 of the study, animals were gonadectomized (GDX) under isoflurane anesthesia. All animals were killed 7 days after GDX. Mice were injected subcutaneously (s.c.) 0.5, 1, 3, 6, 12 or 24 h before death with dihydrotestosterone (DHT) (0.1 mg/mouse) or THG (0.5 mg/mouse). DHT and THG were suspended in 5% ethanol–0.4% methylcellulose. A GDX vehicle-injected group was used as a control. Eight intact mice of the same strain, age and body weight were killed as described above and tissues were collected, weighed and discarded. The mice killed 2, 4 and 7 days after starting treatment received daily injection of the steroids and were killed 24 h after the last injection under isoflurane anesthesia and were exsanguinated via cardiac puncture. The prostate (ventral+dorsal), seminal vesicles, preputial glands as well as gastrocnemius and levator ani muscle were collected, freed from adhering tissue or fluid and weighed.

Synthesis of THG

A mixture of gestrinone (100 mg, 0.324 mmol) and palladium on activated carbon (10% wt) (11 mg) in dichloromethane (50 ml) was stirred under H_2 (1 atmosphere) at room temperature for approximately 60 min. The reaction was monitored by proton nuclear magnetic resonance (^1H NMR). The mixture was filtered through a Celite pad and washed several times with dichloromethane. Solvent was removed by evaporation. The crude product was purified by flash chromatography on silica gel (hexanes–ethyl acetate/9–1 to hexanes–ethyl acetate/8–2) and by flash chromatography on reverse phase gel (C18) (CH_3CN – $MeOH$ – H_2O /10–50–50 to CH_3CN – $MeOH$ – H_2O /30–30–30) to give the desired product (THG) as a yellow foam (47 mg, 47% yield, 98–99% chemical purity by HPLC). ^1H NMR (400 MHz, $CDCl_3$): δ 0.99 (t, $J=7.3$ Hz, 3H), 1.06 (t, $J=7.5$ Hz, 3H), 1.29 (m, 1H), 1.35–1.95 (m, 8H), 1.90 (m, 1H), 2.08 (m, 1H), 2.50 (t, $J=7.3$ Hz, 2H), 2.55–2.65 (m, 3H), 2.85 (m, 2H), 5.79 (s, 1H), 6.38 (d, $J=10.1$ Hz, 1H), 6.59 (d, $J=10.1$ Hz, 1H) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ 7.46, 11.35, 22.58, 24.26, 24.35, 27.12, 30.63, 31.51, 34.34, 36.67, 37.64, 49.02, 50.76, 84.13, 123.49, 124.64, 126.94, 140.84, 142.02, 156.58, 199.26 ppm.

RNA extraction and microarray analysis

Tissues were snap-frozen in liquid nitrogen and kept at $-80^\circ C$ prior to RNA extraction. Total RNA was isolated by Trizol (Invitrogen) and purified with Rneasy Mini Kit columns (Qiagen). The quality of total RNA, cDNA synthesis, cRNA amplification and cRNA fragmentation was monitored by micro-capillary electrophoresis (Bioanalyzer 2100, Agilent Technologies, Mississauga, Ontario, Canada). Twenty micrograms of total RNA were converted to cDNA and transcribed *in vitro* to produce biotinylated cRNA. Fifteen micrograms

Figure 1 Effect of increasing concentrations of methyltrienolone (R1881), testosterone (TESTO), tetrahydrogestrinone (THG) and dihydrotestosterone (DHT) on $[^3H]$ R1881 binding to the human androgen receptor. The incubation was performed with 3 nM $[^3H]$ R1881 for 16 h at $0-4^\circ C$ in the presence or absence of the indicated concentrations of unlabeled compounds.

fragmented cRNA were hybridized for 16 h at $45^\circ C$ with constant rotation (60 r.p.m.). Microarrays were processed using the Affymetrix GeneChip Fluidic Station 400 (Affymetrix, Santa Clara, CA, USA). Staining was carried out with streptavidin-conjugated phycoerythrin (SAPE) followed by an amplification with a biotinylated anti-streptavidin antibody and by a second round of SAPE before scanning using a GeneChip Scanner 3000 (Affymetrix). The signal intensities for the β -actin and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) genes were used as internal quality controls. The ratio of fluorescent intensities for the 5' end and the 3' end of these housekeeping genes was <2 . Hybridization was performed in duplicate to the MOE-430 v2.0 GeneChip set (Affymetrix) according to the Affymetrix protocols. Scanned images were analyzed with Affymetrix GCOS v1.1 software and with GeneSpring 6.1 software (Silicon Genetics, Redwood City, CA, USA) as described (Vasseur *et al.* 2003).

Androgen receptor assay

Preparation of human embryonic kidney (HEK-293) cells stably transfected with human androgen receptor (hAR):

Figure 2 Effect of 7-day daily treatment with DHT or THG on the weights of (A) prostate, (B) seminal vesicle, (C) preputial gland and (D) levator ani muscle in gonadectomized (GDX) male C57BL6 mice. Data are expressed as the mean $\pm$ S.E.M. of 10 animals per group. ** $P < 0.01$, experimental versus GDX-control mice, ++ $P < 0.01$, experimental versus intact control mice.

The pCMV neo-hAR plasmid (Huang & Luu-The 2001) was transfected into HEK-293 cells using a lipofectin transfection kit (Life Technologies, Ontario, Canada), and cells resistant to G418 were isolated as previously described (Dufort *et al.* 1999). On the morning of the binding assay, a pellet of HEK-293 hAR cells was thawed, suspended in buffer, sonicated and centrifuged at $105\,000 \times g$ for 90 min. The androgen binding assay was performed with the hydroxylapatite (HAP) method (Martel *et al.* 1998) using HEK-293 hAR cell cytosol preparation (0.1 ml) and 3 nM [^{3} H]R1881 purchased from Perkin Elmer Life and Analytical Sciences (Ontario, Canada).

Data were expressed as means $\pm$ S.E.M. The statistical significance was determined according to the multiple range test of Duncan–Kramer (Kramer 1956). Microarrays

data were normalized with the bioconductor package, using the MAS5 and RMA normalization methods. Probe sets with an expression ratio higher (or lower) than the variable cut-off point were considered as significantly stimulated (or inhibited). A cut-off point varying with the gene expression intensity was used with the following parameters for the MAS5 method: $Cop = 1.8 + 97/x$ for MAS5, where Cop means the cut-off point and x is equal to the minimum gene expression value in the expression ratio. For the RMA method, a fixed fold change of 1.58 was considered as significant. Only probe sets considered as significantly modulated by both normalization methods at at least one time interval were kept for the clustering analysis. Probe sets were clustered hierarchically with the GeneSpring program version 6.1 (Silicon Genetics, Redwood City, CA, USA) using a Euclidian distance.

Figure 3 (A) and (B).

Results

Since the first step in the action of androgens is binding to the androgen receptor (AR), we first compared the potency of THG with that of DHT, the most potent natural androgen, as well as with testosterone and the synthetic androgen methyltrienolone (R1881), to displace [^{3} H]R1881 from the human AR. As can be seen in Fig. 1, R1881, DHT and testosterone have relative potencies of 72%, 58% and 7% compared with the 100% value set for THG, the compound showing the highest affinity for AR. These data already indicate the potential high androgenic activity of THG.

We next used classical *in vivo* assays to assess the *in vivo* activity of THG. In a preliminary experiment, THG has been found to be 20% as potent as DHT as a stimulator of mouse prostate weight, the most widely used parameter of androgenic activity (Labrie *et al.* 1988) (data not shown). We could then select doses of the two compounds which prevent the inhibitory effect of gonadectomy on accessory sex organ weight, namely 0.1 mg and 0.5 mg daily subcutaneous (s.c.) doses of DHT and THG respectively. In fact, the daily injection of DHT completely reversed the GDX-induced atrophy of the prostate and led to a prostate weight similar to that of intact animals (Fig. 2A). Daily treatment with 0.5 mg THG, on the other hand, reversed

Figure 3 (C).

Figure 3 Comparison of the effect of DHT on the gene expression profile by cluster analysis at 0.5, 1, 3, 6, 12 and 24 h following a single subcutaneous injection of 0.1 mg DHT or 0.5 mg THG or 2, 4 and 7 days following daily administration of the same doses of the two steroids in the (A) levator ani muscle, (B) gastrocnemius muscle and (C) prostate of mice GDX 7 days previously. The genes selected were those identified in common according to the Affymetrix MAS 5.0 and RMA programs (Gautier *et al.* 2004). The color scales representing fold-changes induced by treatments are shown below the panels.

the effect of GDX to a value not statistically different from intact controls. While GDX caused 48% ($P < 0.01$) and 52% ($P < 0.01$) decreases of seminal vesicle (Fig. 2B) and preputial gland (Fig. 2C) weights respectively, the administration of DHT or THG completely reversed the GDX-induced atrophy of both tissues. The levator ani is an androgen-sensitive muscle (Boissonneault *et al.* 1989) which has long been recognized as a myotropic marker of the androgenic/anabolic activity of steroids (Eisenberg *et al.* 1950). While GDX caused a 26% decrease in weight of the levator ani, the injection of DHT or THG increased the weight of the levator ani to values not different from intact animals (Fig. 2D).

The most impressive anabolic activity of THG, however, is illustrated by the very close similarity of the pattern of genes up (red)- as well as down (blue)-regulated by both DHT and THG in the androgen-sensitive muscle levator ani (Fig. 3A). In fact, the expression of 671 genes is significantly modulated in an almost superimposable fashion by both DHT and THG in the mouse levator ani. Although the gastrocnemius muscle is less androgen-sensitive, Fig. 3B shows that 95 genes are commonly modulated by DHT and THG in this tissue, thus resulting

in another clear androgenic signature of THG. On the other hand, in the prostate, the classical androgen-sensitive tissue (Labrie *et al.* 1988), 939 genes are commonly modulated by DHT and THG, thus clearly providing another typical androgenic/anabolic signature of the action of THG (Fig. 3C). Not only are a large number of genes similarly up- or down-regulated in the three tissues by the two steroids but also their time course of action is almost superimposable (Fig. 3). In fact, the majority of changes in the gene expression pattern are seen within the first 24 h, while almost identical pictures are observed at days 2, 4 and 7 since the changes seen on day 2 usually remain on a plateau up to day 7. It is worth noting that not only the time course but also the amplitude of the effects induced by DHT and THG are very close.

It could be seen that the majority of genes/transcripts modulated by the two steroids are in the categories (according to Gene Ontology, www.geneontology.org) of binding, catalytic activity, signal transduction activity, transcription activity, transcription regulatory activity and structural molecule activity. Among the genes that are modulated by both DHT and THG in the three tissues studied, it is worth noting the presence of Fos, a gene

involved in multiple signaling pathways, dual specific phosphatase 1 (DUSP1), and pyruvate dehydrogenase kinase 4 (PDK4), a gene involved in glucose metabolism. MyoD, a marker of muscle differentiation, is also stimulated in the levator ani by both THG and DHT. Among the genes/transcripts found to be modulated by both DHT and THG in the prostate, it is of interest to mention that 69 of these have already been shown to be modulated by DHT in this tissue following quantitative real-time PCR measurement (Q_RTPCR).

Among the modulated transcripts already validated by Q_RTPCR, CAI is a calcium binding protein related to a protein disulfide isomerase, and MAN1A is a mannose oxidase involved in the maturation of Asn-linked oligosaccharides. This enzyme progressively trims α -1, 2-linked mannose residues from Man(9)GlcNAc(2) to produce Man(5)GlcNAc(2). NUCB2 is a calcium-binding protein that belongs to the nucleobindin family. FKBP5 is a drug (FK506)-binding protein possessing peptidyl-prolyl cis-trans isomerase activity which interacts with functionally mature hetero-oligomeric progesterone receptor complexes along with HSP90 and telomerase binding protein p23 (TEBP). SERPINE 2 is a heparin binding protein involved in the regulation of proteolysis and peptidolysis, while arginase 2 (ARG2) is a manganese ion binding protein and metalloendopeptidase (MME) is a zinc binding protein involved in proteolysis and peptidolysis. NCOA4 (ARA70) is a coactivator that interacts with the androgen receptor and RXR, while NKX3-1 is a transcription factor involved in nucleotide and nucleic acid metabolism. RSG2 is a signal transducer of a G-protein coupled with cAMP nucleotide second messenger, while CCL9 is a protein possessing chemokine activity by binding to a G-coupled chemokine receptor. HP (haptoglobin) is a hemoglobin binding protein possessing the signature of a serine protease that has lost all essential catalytic residues and has no enzymatic activity. NANS is an antifreeze-like protein that could bind ice and is involved in the production of N-acetylneuraminic acid (Neu5Ac) and 2-keto-3-deoxy-D-glycero-D-galactononic acid (KDN). MTHFD2 is a bifunctional enzyme containing methylenetetrahydrofolate dehydrogenase and cyclohydrolase activities. This enzyme is involved in folate as well as glyoxylate and dicarboxylate metabolism. On the other hand, 3'-phosphoadenosine 5'-phosphosulfate synthase 2 (PAPSS2) is a bifunctional enzyme with both ATP sulfurylase and APS kinase activities involved in the biosynthesis of 3'-phosphoadenosylphospho sulfate (PAPS) that acts as sulfate donor cofactor for sulfotransferases. BPGM is a biphosphoglycerate phosphatase controlling 2,3-BPG concentration that plays a major role in regulating hemoglobin oxygen affinity, while IDI1, isopentenyl-diphosphate delta isomerase, is an enzyme of the isoprenoid biosynthetic pathway whose end products include dolichols, vitamins A, D, E and K, steroid hormones, carotenoids, bile acids and cholesterol.

Discussion

The power of gene-expression profiling has been clearly demonstrated in clinical medicine by the capability to divide adult acute myeloid leukemia into subgroups having different responses to specific treatments (Bullinger *et al.* 2004, Valk *et al.* 2004), thus permitting the choice of the best treatment for each category of cancer while avoiding the serious side effects of inefficient treatments and the vital time lost trying inappropriate therapy while the cancer continues to progress (Burnett 2002, Mistry *et al.* 2003).

THG is the largest drug scandal in the history of world sport (Kondro 2003). The first drug tests by the IOC were run at the 1968 Olympic Games in Mexico where only ethanol was found, while the first detection of banned drugs was made in six athletes in Munich in 1972. The chemical synthesis of THG was designed to escape detection since the compound degrades during standard gas chromatography and mass spectrometry procedures (Kondro 2003). THG was identified in the laboratory of Donald Catlin at UCLA in June 2003 from a sample sent in a syringe to the US Anti-Doping Agency (Knight 2003b).

THG is clearly not a dietary supplement. The present data show that this steroid has 20% the potency of DHT, the most potent natural androgen. Similarly, dehydroepiandrosterone (DHEA) and androstenedione are not dietary supplements since these two steroids are transformed in the tissues which possess the appropriate enzymatic machinery into the same highly potent androgen DHT (Labrie 1991, Labrie *et al.* 1998, 2003). THG differs from gestrinone by reduction of the ethynyl to an ethyl group at position 17 α . Such a change can translate into unknown differences of biological activity and toxicity. Gestrinone is a compound which possesses androgenic, as well as anti-progestin and some estrogenic activities (Azadian-Boulanger *et al.* 1973, Sakiz *et al.* 1974, Raynaud *et al.* 1975). Gestrinone is used in clinical medicine on a small scale, especially for the treatment of endometriosis (Dawood *et al.* 1997), uterine myoma (De Leo *et al.* 2002) and mastalgia (Peters 1992). The side effects observed with gestrinone include hirsutism, acne, voice changes, weight gain and increased hemoglobin (Coutinho *et al.* 1986, Coutinho 1989). It is expected that THG will also decrease gonadotropin secretion by the anterior pituitary gland as observed in our animal studies with the parent compound gestrinone (Kelly *et al.* 1979), thus leading to inhibition of testicular and ovarian activity in men and women taking THG. Our data also suggest an interaction between androgen action and oxygen consumption as indicated by the activation by DHT and THG of bisphosphoglycerate mutase, which regulates hemoglobin oxygen affinity.

In conclusion, the changes in the genomic profile induced in androgen-sensitive tissues, including muscles,

provide an extremely precise and unquestionable signature of the androgenic/anabolic activity of THG used by athletes to artificially increase their performance. In addition to its potent androgenic/anabolic and progestin (Death *et al.* 2004) activities, the toxicity profile of THG is completely unknown, thus making this compound an unknown risk for human use.
