Abstract

Acute and excessive iodine supplementation leads to iodine-induced thyroid cytotoxicity. Excessive oxidative stress has been suggested to be one of the underlying mechanisms in the development of thyroid cytotoxicity. The aim of this study was to investigate whether vitamin E (VE), an important antioxidant, could ameliorate iodine-induced thyroid cytotoxicity. A goiter was induced in rats by feeding a low-iodine (LI) diet for 12 weeks. Involution of hyperplasia was obtained by administering a twofold physiological dose of iodine in feeding water with or without the supplementation of 25-, 50-, or 100-fold physiological dose of VE in the LI diet for 4 weeks. In iodine-supplemented rats, thyroid epithelial cell ultrastructure injuries remained and were more severe. Relative weights of iodine-induced involuting glands were significantly reduced compared with the goiter, but still higher than control. Immunohistochemistry indicated that the expression of 4-hydroxynonenal, 8-hydroxyguanine, peroxiredoxin 5, and CD68 in thyroid increased (P<0.01), whereas thioredoxin reductase 1 decreased (P<0.01). VE supplementation attenuated thyroid cytotoxicity induced by iodine. A 50-fold VE dose was optimal in attenuating twofold iodine-induced thyroid cytotoxicity. However, VE supplementation did not reduce the weight or relative weight of the iodine-induced involuting gland. These results show that excess iodine leads to thyroid damage and VE supplementation can partly ameliorate iodine-induced thyroid cytotoxicity.

Introduction

Thyrocytes constantly produce moderate amounts of reactive oxygen species (ROS), which are physiologically required for thyroid hormone synthesis (Denef et al. 1996, Song et al. 2007). Nevertheless, when ROS are over-produced, they may become toxic and damage cell structures and macromolecules including lipids, proteins, and nucleic acids. 4-Hydroxynonenal (4-HNE) is a toxic product resulting from lipid peroxidation and 8-hydroxyguanine (8-OHdG) and is a maker for DNA and RNA damage. A toxic effect of iodide given to iodine-deficient laboratory animals was first noted by Follis (1959). Similar studies have shown that 4-HNE is increased in goitrous and in iodine-induced involuting glands (iodine replenishment for 3 days, acute effects), indicating that oxidative stress (OS) is greatly enhanced in these conditions (Poncin et al. 2008). Increased OS is not necessarily lethal to goitrous cells but is associated with cellular destruction and inflammation in iodine-induced thyroid involution (Mutaku et al. 2002, Poncin et al. 2008).

It is therefore crucial for thyrocytes to develop protective mechanisms that limit the toxicity of endogenous and exogenous ROS. Fortunately, several antioxidants including superoxide dismutases, catalase, glutathione peroxidases (GPxs), peroxiredoxins (PRDXs), thioredoxin reductase (TrxR), and vitamin E (VE) are constitutively expressed in the thyroid (Mutaku et al. 2002, Gerard et al. 2005, Kohrle et al. 2005, Schweizer et al. 2008). Without these antioxidants, it would not be possible for these cells to remain viable and function properly. PRDX5 is a thioredoxin peroxidase that reduces or converts H2O2 into H2O and regulates intracellular levels of peroxides and peroxynitrites (Dubuisson et al. 2004, Banmeyer et al. 2005). PRDX5 is expressed in the cytosol of control thyrocytes as described previously in humans and rats (Gerard et al. 2005, Poncin et al. 2008, 2010). During their catalytic cycle, PRDXs (except PRDX6) are reduced by thioredoxins, which is reduced by TrxR (Lillig & Holmgren 2007). Thioredoxin–TrxR pairs are ubiquitously expressed in the thyroid. Previous data from our laboratory indicate that iodine supplementation, to a level of...
more-than-adequate, in a region in which iodine intake was mildly deficient may accelerate the development of subclinical hypothyroidism to overt hypothyroidism (Teng et al. 2006). The iodine containing drug amiodarone has been found to induce thryotoxicosis in geographical areas with iodine deficiency (Martino et al. 1984, Stanbury et al. 1998). Animal experiments indicate that chronic (iodine replenishment for several weeks) and adequate, more-than-adequate, or excessive iodine supplementation alone to iodine-deficient thyroids cannot cure iodine deficiency-induced injuries; on the contrary, excessive iodine supplement exacerbates thyroid damage (Chong et al. 2005, 2006). Furthermore, antioxidant protection of the thyroid may be impaired by excessive iodine supplementation (Zhang et al. 2006). These findings suggest that excessive OS is one of the underlying mechanisms in the development of iodine-induced thyroid cytotoxicity. VE is classified as an antioxidant due to its ability to scavenge free radicals and terminate lipid oxidative chain reactions. VE has been demonstrated to protect against human diabetes mellitus with the Hp 2-2 phenotype, idiopathic retinal peripheralis, thalassemia, cerebral ischemia/reperfusion injury in irradiated rats, and steroid-induced osteonecrosis in rabbits (Milman et al. 2008, Abd-El-Fattah et al. 2010, Fibach & Rachmilewitz 2010, Mikami et al. 2010, Saxena et al. 2010). VE, which is also very active in the antioxidative protection of thyrocyte membranes, is as concentrated in the thyroid as in the liver in control rats and is increased twofold in goiters (Mutaku et al. 1998). This indicates that VE is highly increased in the thyroid in cases of enhanced OS.

Unlike other experiments, in this study we used a low-iodine (LI) diet, without propylthiouracil (PTU) or perchlorate, to initiate goiter formation and then long-term small dose of iodine was administered (iodine replenishment for 4 weeks, chronic effects) to induce goiter involution (Chong et al. 2005, 2006a,b, Zhang et al. 2006). VE is a well-established antioxidant; however, it has never been reported to ameliorate thyroid injury induced by small doses of iodine. The purpose of this study was twofold: 1) to investigate OS and antioxidants expression, as well as ultrastructure changes of thyrocytes in a rat model of goiter formation and iodine-induced involution and 2) to examine the potential of VE protection on iodine-induced thyroid cytotoxicity.

Materials and Methods

Animals and experiment protocol

Hyperplastic goiter was induced in 4-week-old female Wistar rats (SLAC Laboratory Animal, Shanghai, China) by feeding a LI diet (dose of iodine in the LI diet is 60 μg/kg) (Institute of Endocrinology, China Medical University, Shenyang, China) and demineralized water for 12 weeks. The weight of the rats and

Figure 1 Thyroid morphology is an experimental model of goiter formation and excess iodine-induced involution supplemented with/without VE (A–F). (A) Thyroids from control rats had cubical epithelial cells and follicular lumina were filled with colloid. (B) Goitrous thyroids had markedly enlarged blood vessels (arrow), hypertrophied epithelial cells, and narrow follicular lumina (*). (C) Thyroids of 2I-induced involution demonstrated constricted blood vessels, widened follicular lumina, and some necrotic cells in lumina (arrowhead). (D–F) Thyroids with 25VE, 50VE, and 100VE supplementation on 2I-induced involution rats showed regular follicles with colloid filled in their lumina. There was less cellular debris and no necrotic cells in the follicular lumina. Scale bar = 20 μm. Thyroid ultrastructure in the experimental model of goiter formation and 2I-induced involution supplemented with/without VE (A’–F’). (A’) Control thyroids (×6400). Nuclei (two-way arrow) were round or ellipse. Endoplasmic reticulum (arrow) was deplanate. There were many ribosomes, mitochondria (arrowhead), colloid droplets, and lysosomes in cytoplasm. Plenty of microvilli were visible in the plasmalemma. (B’) Thyroids of LI-induced goiter (×2500) showed irregular nuclei (two-way arrow) and many incisures. Endoplasmic reticulum (arrow) was hypertrophied with very dilated cisternae and degranulated ribosomes. Mitochondria (arrowhead) had swelling and follicular lumina were not present. (C’) Thyroids from 2I-induced involution rats (×5000) demonstrated that endoplasmic reticulum cisternae (arrow) were much more dilated than goitrous thyroid. Some structures ruptured and were visible as unconnected vacuoles and large cavitation bubbles. Mitochondrial (arrowhead) swelling was increased, and mitochondrial cristae were blurred or even vacuolated (*), with giant mitochondria presented. In three VE-supplemented thyroid involution groups (LI-2I+VE:D’, LI-2I+25VE, ×6000; E’, LI-2I+50VE, ×8000; F’, LI-2I+100VE, ×8000) mitochondria (arrowhead) were swollen and endoplasmic reticulum (arrow) was dilated and ameliorated.
was \( \sim 80 \) g at the onset of the study. Involvement of hyperplasia was obtained by feeding water with a twofold physiological dose of iodine (a twofold iodine (2I) dose in water is \( 470 \times 7 \) mg/l, and rats drank \( \sim 20 \) ml water/day) and LI diet with/without 25-, 50-, or 100-fold the physiological dosage of VE (25VE, 1875 IU/kg; 50VE, 3750 IU/kg; or 100VE, 7500 IU/kg) for 4 weeks (\( n=8 \) per group). The VE dosages were based on previous reports by Many et al. (1991). To validate the experimental model and verify its reproducibility compared with previously published studies (Chong et al. 2005, 2006a,b, Zhang et al. 2006), the morphology of goitrous thyroids was examined as shown in Fig. 1B. The control group received a LI diet and water with normal iodine. Animals were killed using chloral hydrate. Rats were maintained in accordance with the principles of laboratory animal welfare. They were housed four per cage in a temperature- and light-controlled room and had free access to water and their respective diets. Each experimental setting was repeated twice. All procedures were approved by the local ethics committee.

**Weight and relative thyroid weight**

In total, eight animals per group were weighed prior to anesthesia. Thyroids were dissected, washed in cold physiological saline, blotted with filter paper, and weighed. The relative thyroid weight is calculated as the thyroid weight normalized to 100 g body weight.

**Electron microscope studies**

The right lobe of the thyroids was rapidly excised 1 mm\(^3\) and immersed in a 2.5% glutaraldehyde solution at 4 \( ^\circ \)C. After fixation, thyroid fragments were washed three times in cacodylate buffer, postfixed for 2 h in 1% osmium tetroxide, dehydrated in 50 and 70% alcohol solutions, then 80 and 90% acetone solutions each for 30 min, and finally in 100% acetone for three times and for 10 min. Thyroid fragments were embedded in Epon812 and aggregated in incubation at 80 \( ^\circ \)C for 24 h at each temperature. Super-thin sections (0.05 \( \mu m \)) were cut (LKB-V, Bromma, Sweden) and stained with uranyl acetate and lead citrate and examined using a transmission electron microscope (H-600; Hitachi).

**Immunohistochemistry**

The left lobes were fixed in 4% paraformaldehyde and embedded in paraffin. Sections (5 \( \mu m \)) were stained with hematoxylin–eosin or used for immunohistochemistry (IHC). CD68, 4-HNE, 8-OHdG, TrxR-1, and PRDX5 immunostains were performed on 5 \( \mu m \)-thick paraffin sections on Super Frost glass slides (Hehglass, Haimen, China). Sections were dewaxed and rehydrated and treated for endogenous peroxidase with 3% \( H_2O_2 \) for 10 min. Except for PRDX5 detection, tissue sections were pretreated in a microwave oven in citrate buffer (pH 6.6) for 3 min at high power. All sections were washed with PBS and thereafter incubated with blocking sera for 30 min in a 37 \( ^\circ \)C water bath. Sections were incubated with the primary antibodies (CD68, sc-70760, 1:50; 4-HNE, sc-130083, 1:50; 8-OHdG, sc-66036, 1:50; TrxR-1, sc-28321, 1:50; PRDX5, or sc-133072, 1:50) at 4 \( ^\circ \)C overnight. All antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). The binding of antibodies was detected using biotinylated secondary antibodies (Maixin, Fuzhou, China) for 30 min in a 37 \( ^\circ \)C water bath. Peroxidase activity was visualized by 3,3’-diaminobenzidine tetrahydrochloride (Sigma). Sections were counter-stained with Mayer’s hematoxylin, rinsed, and mounted in neutral gum (China National Medicines Corporation Ltd, Shanghai, China). To verify binding specificity, some sections were incubated with the secondary antibodies alone as there are no primary antibody controls. CD68-positive cells (monocytes and macrophages) were counted and reported as numbers per visual field. The expression of other proteins was determined by image information object definition (IOD) values analyzed by Image-Pro Plus 5.0 (Media Cybernetics, Silver Spring, MD, USA).

**Statistical analysis**

Data were analyzed using SPSS 17.0 software (Chicago, IL, USA) and expressed as mean \( \pm \) s.d. A two-sample t-test was used for comparison between two groups, and ANOVA was used for multi-group comparison. \( P<0.05 \) was considered significant.

**Results**

**Histomorphology of thyroid gland before and after iodine-induced involution**

After 16 weeks of goitrogenic treatment, weight and the relative weight of the thyroids were significantly increased (Fig. 2A and B). The thyroid gland was hypervascularized and mainly consisted of hypertrophied follicular cells, whereas colloid had almost disappeared (Fig. 1B). Lysosomes were present and appeared normal. However, the endoplasmic
reticulums (ERs) were hypertrophied with dilated cisternae and mitochondria were swollen. Microvilli were less developed than that in follicular cells of control thyroids. Nuclei were irregular (Fig. 1B). After 4 weeks of a twofold physiological dose of iodine supplementation, the weight and the relative weight of thyroid decreased; however, they were still higher than the control (Fig. 2A and B). Follicular lumina were enlarged and contained more colloid. Blood capillaries were constricted with scattered dead or fragmented cells in the follicular lumina. The interstitium was infiltrated with inflammatory cells (Fig. 1C). ER cisternae were much more dilated than that seen in the goitrous thyroid. Ruptured structures were present and formed unconnected vacuoles and large cavitation bubbles. There was an increase in inflammatory cells (Fig. 1C). ER cisternae were much more

**OS and inflammation**

4-HNE, a toxic product of lipid peroxidation, was used as a marker for the OS. Weak constitutive 4-HNE immunostaining was detected in control thyroids (Fig. 3B), which was occasionally expressed in the plasma membrane and cytoplasm. 4-HNE expression was weaker in goiters but stronger in iodine-induced involutions ($P<0.01$; Fig. 3C and D). The expression was evident in most of the plasma membrane and cytoplasm in iodine-induced involuting glands. The 4-HNE expression was significantly weaker in the 25- and 50-fold VE-treated rats ($P<0.05$) but not in 100-fold VE-treated rats (Fig. 3E–G).

8-OHdG is a marker of RNA and DNA oxidative damage. IHC revealed that 8-OHdG was expressed in perinuclei cytoplasin in control thyroids (not shown). Its expression was diffuse in cytoplasin of goitrous thyroids (not shown). In iodine-treated animals, the staining was significantly more pronounced and more diffuse throughout the cytoplasm as well as some nuclei and interstitium (not shown). However, in three VE supplement groups, the 8-OHdG staining was significantly suppressed, especially in those groups receiving 50- and 100-fold levels of physiological VE ($P<0.01$) (not shown).

An antibody to CD68 was used to identify monocyte and macrophage infiltration. There were very few CD68-positive cells in control thyroids (Fig. 4B). In contrast, many positive cells were found in the thyroids of goitrous ($P<0.01$ versus control) and iodine-treated goitrous rats and were particularly higher in the latter group ($P<0.01$ versus LI; Fig. 4C and D). They were mostly localized in the interstitium, but also in capillaries, vascular lumina, and arterial walls. CD68-positive cells were also detected in VE supplement rats but to a significantly lower degree compared with LI+2I group ($P<0.01$ for 25VE, 50VE, and 100VE groups) (Fig. 4E–G).
Antioxidant enzyme expression

TrxR-1 is an important antioxidant found in the thyroid. It was primarily expressed in the cytoplasm of thyrocytes in control thyroids (Fig. 5B). The staining was less prominent but more diffused throughout the cytoplasm in thyroids of goitrous rats (Fig. 5C). The signal was further suppressed in the thyroids of iodine-induced involuting rats, and this decrease was significant (Fig. 5D). VE treatment restored TrxR-1 expression in the twofold physiological dose of iodine-induced involution groups (*P<0.01 for 25VE and 50VE; *P<0.05 for 100VE versus LI group; Fig. 5E–G).

Another antioxidant, PRDX5, was also weakly expressed in the cytoplasm of control thyrocytes (Fig. 5B). The staining was stronger in goitrous thyroids (*P<0.01 versus control; Fig. 5C). In 2I-induced involuting thyroids (LI-2I), the cytoplasm and numerous nuclei were labeled. Weak expression was observed in the interstitium. In iodine-treated rats, the staining was less pronounced and more diffuse throughout the cytoplasm as well as in the cytoplasm and some nuclei (Fig. 5D). In the 50-fold physiological dose of VE-treated animals (Fig. 5F), the expression of PRDX5 was weak as that seen in control rats. In the 25- and 100-fold physiological dose of VE-treated rats (Fig. 5E' and G'), the staining was also weaker than that in the LI group, but significantly greater than that in rats treated with the 50-fold physiological dose of VE. PRDX5 localization was predominantly interstitial and cytosolic with some nuclear staining. The IOD value of PRDX5 was low in control animals. The expression was significantly increased in hyperplastic and iodine-induced involuting glands; although the expression was lower in the latter group. It was decreased in three VE supplementation groups, especially in rats treated with the 50-fold physiological dose of VE (Fig. 5A').

Discussion

Evidence accumulated over the last several decades indicates that the administration of iodide to goiters provokes thyroid cell necrosis/apoptosis and glandular inflammation (Many et al. 1995, Mutaku et al. 2002, Poncin et al. 2008). Table salt has been iodized throughout China since 1996. Our prospective epidemiological study found that iodine supplementation to a level that is more than adequate in a region where iodine intake was previously mildly deficient may accelerate the development of subclinical hypothyroidism to overt hypothyroidism (Teng et al. 2006). Because of the risks associated with iodine-supplementation to iodine-deficiency
Goiter and the necessity for iodine supplementation to prevent and treat iodine-deficiency disorders, we need to optimize iodine supplementation and find a way to alleviate or avoid potential iodine-induced thyroid cytotoxicity. VE is an important factor for the cellular protection of membrane lipid peroxidation. In this study, excess iodine (twofold physiological dose) did lead to thyroid cytotoxicity and at least partially alleviated iodine-induced cytotoxicity, possibly through regulating OS, antioxidant defenses, and the inflammatory reaction.

In contrast to previous studies (Poncin et al. 2008, 2010), we observed that OS was decreased in goitrous thyrocytes. The following points may explain this discrepancy. First, antioxidant PRDX5 expression was significantly higher in goitrous glands compared with control, which could play a role in regulating ROS levels in intact thyrocytes. Secondly, Song et al. (2007) have suggested that thyroid peroxidase (TPO) has a catalase-like effect in the absence of iodide; it oxidizes other potential available substrates depending on their specific affinities and thus catabolizes H₂O₂. Fang et al. (2001) have demonstrated that TPO mRNA expression was increased in goiters, which is consistent with our previous study that suggested TPO activity was significantly higher in goiters than in control (A Stone, unpublished observations). Our goitrous gland model was achieved by administering a LI diet without PTU in rats, which suppresses the activity of TPO. This suggests that higher TPO activity may cleave free radicals such as H₂O₂ when their levels accumulate in long-term iodine deficiency. Finally, Mutaku et al. (1998) have demonstrated that cell necrosis increased as early as 8 days after goiter induction and returned to control levels by day 32, which was in line with our findings in the rat goiter model induced for 12 or 16 weeks.

Different from goitrous glands, hyperplastic thyrocytes treated with a twofold physiological dose of iodide were severely injured as shown by the membrane rupture, formation of ER vesicles, mitochondrial swelling, and massive inflammatory response. All of these changes have
also been found in onefold dose iodine-treated goiter rats in our laboratory (A Stone, unpublished observations). The acuteness of cellular damage was specifically due to iodine-induced toxicity and not to the inovation process, which had been supported by T4-induced involution (Poncin et al. 2008). In chronic and twofold dose iodine-treated rats, OS was significantly higher and accompanied by a stronger inflammatory reaction compared with goitrous animals, which is consistent with the findings of Poncin et al. (2008). However, the exact underlying mechanism for excess iodine-induced toxicity in goitrous animals is unclear. Corvilain et al. (2000) have found that iodide has a stimulatory effect on H2O2 generation, thereby increasing OS. Iodine-induced cytotoxicity may be due to increased free radicals and more severely altered antioxidant defenses compared with goiter (Poncin et al. 2008). We observed that TrxR-1 and PRDX5 (both are important antioxidants in the thyroid) were expressed at significantly lower levels in iodine–treated rats than goitrous rats, suggesting that these antioxidants may fail to detoxify a heavier load of ROS or that they are depleted by an overload of ROS. Whereas thyroid antioxidant systems are naturally adapted to detoxify excess H2O2 produced in TSH-stimulated thyrocytes, they may be overwhelmed by a heavier and more severe free radical storm–like attack (lipid peroxides, singlet oxygen, superoxide anions, hydroxyl radicals, peroxynitrites, etc.). This hypothesis is in accordance with previous work that demonstrated that tissue damage is markedly enhanced when iodide is supplied to goitrous thyrocytes with impaired antioxidant systems (Contempre et al. 1993, 2004, Mutaku et al. 2002).

Our previous data indicated that selenium may increase antioxidant defenses and partly alleviate iodine-induced thyroid cytotoxicity (A Stone, unpublished observations). In this study, we investigated whether other antioxidants could alleviate iodine-induced cytotoxicity. VE plays a major role in the maintenance of membrane integrity, being both a potent free radical scavenger and a structural stabilizer (Gutteridge 1978). VE deficiency in the thyroid leads to increased malondialdehyde concentration, decreased GPx activity, induction of colloid accumulation and cell debris during goiter involution, and aggravation of epithelial cell necrosis (Mutaku et al. 2002). VE can protect thyrocyte membranes, and it is as concentrated in the thyroid as in the liver in control rats and is increased twofold in goiters (Mutaku et al. 1998). We speculated that the increased concentration of VE in goiter thyroid may compensate for the increased levels of OS. In the 25- and 50-fold physiological dose VE–treated groups, the expressions of 4-HNE and 8-OHdG were significantly decreased. The 100-fold physiological dose of VE decreased the expression of 8-OHdG, but 4-HNE remained significantly higher than that observed in the iodine–treated group. Although VE is an antioxidant, overdose may increase OS (Bouayed & Bohn 2010). VE alleviated the over-activated OS induced by iodine. The expression of TrxR–1 was significantly higher in all three VE supplementation groups compared with the iodine–treated group, which suggests that VE may alleviate ROS by upregulating TrxR–1. However, PRDX5 expression was decreased in all three VE supplementation groups, especially in the 50-fold group (P < 0.01), compared with LI group. Previous studies indicated that the administration of N-acetylcysteine, a potent antioxidant, reduces PRDX5 expression in the thyroid (Poncin et al. 2010), therefore we presume that VE may act in the same manner.

In conclusion, long-term supplementation using a twofold dose of iodine may induce iodine-deficient thyroid involution, and lead to iodine-induced thyroid cytotoxicity. Excessive OS may play an important role in the pathophysiology of iodine-induced thyroid toxicity. VE may increase thyroid antioxidant defenses and inhibit iodine-induced thyroid cytotoxicity. Further studies are needed to verify the optimal dose of VE supplementation for ameliorating the potential side effects of universal salt iodization.
