Abstract

The corticosterone (CORT) level changes along the circadian rhythm. Hippocampus is sensitive to CORT, since glucocorticoid receptors are highly expressed. In rat hippocampus fixed in a living state every 3 h, we found that the dendritic spine density of CA1 pyramidal neurons increased upon waking (within 3 h), as compared with the spine density in the sleep state. Particularly, the large-head spines increased. The observed change in the spine density may be due to the change in the hippocampal CORT level, since the CORT level at awake state (~ 30 nM) in cerebrospinal fluid was higher than that at sleep state (~ 3 nM), as observed from our earlier study. In adrenalectomized (ADX) rats, such a wake-induced increase of the spine density disappeared. S.c. administration of CORT into ADX rats rescued the decreased spine density. By using isolated hippocampal slices, we found that the application of 30 nM CORT increased the spine density within 1 h and that the spine increase was mediated via PKA, PKC, ERK MAPK, and LIMK signaling pathways. These findings suggest that the moderately rapid increase of the spine density on waking might mainly be caused by the CORT-driven kinase networks.

Introduction

Corticosterone (CORT), known as a stress hormone, is released from the adrenal cortex, and the plasma CORT level is regulated by adrenocorticotrophic hormone (ACTH) stimulation. ACTH is secreted from the pituitary gland in response to the arrival of the corticotropin-releasing hormone, which is released from the paraventricular hypothalamic nucleus (PVN). Since PVN has direct and indirect projections from the suprachiasmatic nucleus (Buijs *et al.* 1993, Vrang *et al.* 1995), the CORT level changes in both the plasma and brain along the circadian rhythm (Migeon *et al.* 1956, Moore & Eichler 1972, Qian *et al.* 2012).

Qian *et al.* showed the high synchronicity of CORT oscillation between the blood and hippocampus by using microdialysis. Our previous study showed that in the cerebrospinal fluid (CSF), the CORT concentration is ~ 30 nM in the awake state and ~ 3 nM in the sleep state (Higo *et al.* 2011). These concentrations are much lower than the stress level of CORT (~ 1 μ M), which causes neural atrophy and memory impairments (Woolley *et al.* 1990, Krugers *et al.* 1997). Compared to the stress level of CORT (~ 1 μ M), the physiological functions from the lower level CORT (~ 30 nM) almost remain unraveled. We also do not

know the role of the diurnal rise and fall of such a low level CORT in the brain.

The hippocampus, the center for learning and memory, is particularly sensitive to CORT (Kim *et al.* 2006, Maggio & Segal 2010) because glucocorticoid receptors (GR) are abundantly expressed in the hippocampus (Chao *et al.* 1989, Morimoto *et al.* 1996). The hypothalamic–pituitary–adrenocortical axis (mentioned above) receives feedback regulation from the hippocampus (Sapolsky *et al.* 1984, Jacobson & Sapolsky 1991). Recent studies show that the performance of hippocampal-dependent learning and memory fluctuates along the circadian rhythm. The scores on the novel-object recognition task are higher during the dark phase (awake state) than during the light phase (sleep state) (Ruby *et al.* 2008). The performance of the motor skill learning (cortex-dependent) is also better in the awake state (Liston *et al.* 2013), and this diurnal change has a strong relationship with the circadian CORT oscillation. Liston *et al.* demonstrated that the spine (postsynaptic structure) formation of pyramidal neurons in the motor cortex is enhanced by circadian CORT peaks. The spinogenesis of hippocampal pyramidal neurons is also induced by the treatment of CORT on isolated hippocampal slices (Komatsuzaki *et al.* 2012, Yoshiya *et al.* 2013). In these studies, however, 200–10 000 nM CORT is administrated to increase spines, which is a much higher level than the CORT level in CSF during the circadian CORT peaks (~30 nM). Therefore, the effect from the lower physiological level of CORT on spines should be revealed.

In the current study, we investigated whether the spine density in the CA1 region of the hippocampus changes along the diurnal sleep–wake cycle and whether the circadian rhythm of CORT causes it. We also examined the effect by the treatment of 30 nM CORT on the spine density in the isolated hippocampal slices. The time course of the CORT effect and its signaling cascade within the downstream of the synaptic GR were investigated. We provided detailed understanding of how the diurnal rise in CORT influences dendritic spines in the hippocampus.

Materials and methods

Animals

Young adult male Wistar rats (10–11 weeks old, 280–320 g) were purchased from Tokyo Experimental Animals Supply (Tokyo, Japan). All animals were maintained under a 12 h light:12 h darkness cycle (lights on at 0800 h, lights off at 2000 h) and given free access to food and water. The rats were adapted to light–dark conditions for 1 week before the

experiments. The Zeitgeber time 0 (ZT0) was designated as lights on, and ZT12 was designated as lights off. Rats fall asleep around ZT0 and wake up around ZT12. The experimental procedure of this research was approved by the Committee for Animal Research of the University of Tokyo.

Chemicals

Lucifer Yellow, CORT, Metyrapone, RU-486, Spironolactone, U0126, and SP600125 were purchased from Sigma–Aldrich. Actinomycin D and cycloheximide (CHX) were from Wako Pure Chemical Industries (Osaka, Japan). H-89 was from Biomol (Philadelphia, PA, USA). Chelerythrine and LIM kinase inhibitors were from Calbiochem (Cambridge, MA, USA).

Adrenalectomy and s.c. drug administration

The adrenal glands from 11-week-old male rats were removed bilaterally under deep anesthesia. The rats were given the time to recover from operations and then placed in cages with 0.9% saline (for maintaining electrolyte balance) and food. These surgeries were performed 1 week before the experiments.

Metyrapone (50 mg/kg body weight) was dissolved in DMSO and diluted with sesame oil to reach its appropriate concentration, enough to suppress the increase of endogenous CORT (Rooszendaal *et al.* 1996). The final volume was adjusted to 400 µl. S.c. administration was performed at ZT9, 4 h before the decapitation. During the injection, the rats were gently handled by the experimenter. Similarly, CORT (1 mg/kg body weight) was injected subcutaneously into adrenalectomized (ADX) rats at ZT11, 2 h before the decapitation.

Imaging and analysis of dendritic spine density

Slice preparation (from *in vivo* fixed hippocampus)

Hippocampal slices were prepared from a 12-week-old male rat that was deeply anesthetized and perfused transcardially with PBS (0.1 M phosphate buffer and 0.14 M NaCl, pH 7.3), followed by a fixative solution of 3.5% paraformaldehyde. Immediately after decapitation, the brain was removed from the skull and post-fixed with the fixative solution. Hippocampal slices, 400 µm thick, were sliced with a vibratome (Dosaka, Kyoto, Japan).

Slice preparation (from isolated hippocampus) Twelve-week-old male rats were deeply anesthetized. Decapitation

was performed without paraformaldehyde fixation procedures. Immediately after decapitation, the brain was removed from the skull and placed in ice-cold oxygenated (95% O₂ and 5% CO₂) artificial CSF (ACSF) containing the following (in mM): 124 NaCl, 5 KCl, 1.25 NaH₂PO₄, 2 MgSO₄, 2 CaCl₂, 22 NaHCO₃, and 10 D-glucose (all from Wako Pure Chemical Industries); pH was set at 7.4. Hippocampal slices, 400 µm thick, were sliced with a vibratome. During this moment, these slices were 'fresh' slices without the ACSF incubation. Slices were then incubated in oxygenated ACSF for 2 h (slice recovery processes) to obtain the widely referred 'acute slices' (Supplementary Fig. S1, see section on [supplementary data](#) given at the end of this article). These 'acute slices' were then incubated at room temperature with CORT and other drugs, including kinase inhibitors. After drug exposure, slices were fixed with 4% paraformaldehyde at 4 °C for 4 h.

Current injection of neurons by Lucifer Yellow Neurons within slices were visualized by an injection of Lucifer Yellow under a Nikon E600FN microscope (Tokyo, Japan) equipped with a C2400-79H infrared camera (Hamamatsu Photonics, Shizuoka, Japan) and 40× water immersion lens (Nikon). A glass electrode was filled with 4% Lucifer Yellow, which was then injected for 5 min using Axopatch 200B (Axon Instruments, Foster City, CA, USA). With this process, approximately five neurons within a 100–200 µm depth from the surface of a slice were injected ([Huang et al. 2005](#), [Hanani 2012](#)).

Confocal laser microscopy and spine density analysis The imaging was performed from sequential z-series scans with LSM5 PASCAL confocal microscope (Zeiss, Jena, Germany) at high zoom (3.0) with a 63× water immersion lens, NA 1.2 (Zeiss). For Lucifer Yellow, the excitation and emission wave lengths were 488 and 515 nm respectively. For an analysis of spines, a three-dimensional image was reconstructed from ~40 sequential z-series sections for every 0.45 µm. The applied zoom factor (3.0) yielded 23 pixels/1 µm. The confocal lateral (XY) resolution was ~0.26 µm. Confocal images were then deconvoluted using AutoDeblur Software (AutoQuant, Rockville, MD, USA).

The density of spines was analyzed with Spiso-3D (mathematical and automated software calculating geometrical parameters of spines), developed by the Bioinformatics Project of Kawato's group ([Mukai et al. 2011](#)). Spiso-3D has an equivalent capacity with NeuroLucida (MicroBrightField, Williston, VT, USA), which, however, needs time-consuming manual operation. We

analyzed the spines in the CA1 pyramidal neurons, along apical dendrites in stratum radiatum of the dorsal hippocampus. We chose the secondary dendrites that were 100–250 µm away from the soma. The spine density was calculated from the number of spines per unit length in the dendrite that had a total length of 50–60 µm.

Spine shapes were classified into three categories as follows: i) a small-head spine, whose head diameter is smaller than 0.4 µm; ii) a middle-head spine, which has 0.4–0.5 µm spine head; and iii) a large-head spine, whose head diameter is larger than 0.5 µm. These three categories were useful to compare the distribution of spine head diameters in each condition. Because the majority of spines (>95%) had a distinct head and neck, and stubby spines and filopodium did not contribute much to overall changes, we mainly analyzed spines with distinct heads. While counting the spines in the reconstructed images, the position and verification of spines were identified by the rotation of three-dimensional reconstructions and observation of the images in consecutive single planes.

Mass-spectrometric assay of CORT

Detailed procedures are described elsewhere ([Hojo et al. 2009](#)).

Step 1: purification of CORT from hippocampi with normal phase HPLC A rat was deeply anesthetized and decapitated. The whole hippocampi was removed and homogenized. To extract steroid metabolites, ethyl acetate:hexane (3:2 vol/vol) was applied to the homogenates, which were then mixed. The mixture was centrifuged at 2500 g, and the organic layer was collected. After evaporation, the extracts were dissolved in 1 ml of 40% methanol/H₂O and applied to a Sep-Pak C₁₈ 3 cc Vac Cartridge (Waters, Milford, MA, USA). The fraction of CORT was separated using a normal phase HPLC system (Jasco, Tokyo, Japan). A silica gel column (Cosmosil SSL, Nacalai Tesque, Kyoto, Japan) was used.

Step 2: determination of the concentration for CORT using liquid chromatography–tandem mass spectrometry For determination of the concentration of CORT, the liquid chromatography–tandem mass spectrometry (LC–MS/MS) system, which consists of the Shimadzu HPLC system and an API-5000 triple-stage quadrupole mass spectrometer (Applied Biosystems), was employed. LC separation was performed on a Cadenza CD-C₁₈ column (Imtakt, Kyoto, Japan). MS analysis was operated with electrospray ionization in positive-ion mode. In multiple reaction monitoring

mode, the instrument monitored the m/z transition from 347 to 121 for CORT. Here, m and z represent the mass and charge of CORT respectively.

The limit of quantification for CORT was 2 pg/0.1 g of hippocampal tissue (Higo *et al.* 2011). From the calibration curve using standard CORT dissolved in blank samples, the linearity was observed between 1 and 1000 pg for CORT (Supplementary Fig. S2, see section on supplementary data given at the end of this article).

Statistical analysis

Data are expressed as mean $\pm$ S.E.M. For analysis of the spine density, we used a one-way ANOVA followed

by Tukey–Kramer *post hoc* multiple comparisons test. A difference was considered significant at a value of $*P < 0.05$ or $**P < 0.01$.

Results

Spine density showed diurnal change in the *in vivo* fixed hippocampus

We investigated the diurnal change of dendritic spine density in the hippocampus. Lucifer Yellow-injected neurons in hippocampal slices from 12-week-old male rats were imaged using confocal laser scan microscopy (Fig. 1A). We analyzed secondary branches in the apical

Figure 1

Diurnal change of the spine density in hippocampal CA1 pyramidal neurons. Spines were analyzed along the secondary dendrites of CA1 pyramidal neurons in the stratum radiatum every 3 h. (A) Representative images of confocal micrographs; the spines along dendrite at Zeitgeber time 4 (ZT4, 1200 h), ZT10 (1800 h), ZT13 (2100 h), and ZT16 (2400 h). Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μ m. (B) Diurnal change of the total spine density in the hippocampus. Vertical axis represents the average number of spines per 1 μ m of dendrite. Data are represented as mean $\pm$ S.E.M. (C) Histogram of spine head diameters at ZT4 (closed white circle), ZT10 (closed blue circle), ZT13 (closed black circle),

and ZT16 (closed green circle). (D) Density of three subtypes of spines at ZT1 (yellow column), ZT4 (white column), ZT7 (red column), ZT10 (blue column), ZT13 (black column), ZT16 (green column), ZT19 (orange column), and ZT22 (purple column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean $\pm$ S.E.M. The statistical significance was examined using one-way ANOVA followed by the Tukey–Kramer *post hoc* multiple comparisons test. The significance yielded: $**P < 0.01$, $*P < 0.05$ vs 'ZT10'. For each period of time, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~6000–8000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

dendrites located 100–250 μm away from the pyramidal cell body and in the middle of the stratum radiatum in the CA1 region.

Total spine density analysis The total spine density showed the time-dependent change as follows: 2.10 spines/ μm (ZT1, 0900 h), 2.10 spines/ μm (ZT4, 1200 h), 2.09 spines/ μm (ZT7, 1500 h), 2.14 spines/ μm (ZT10, 1800 h), 2.49 spines/ μm (ZT13, 2100 h), 2.28 spines/ μm (ZT16, 2400 h), 2.30 spines/ μm (ZT19, 0300 h), and 2.19 spines/ μm (ZT22, 0600 h) (Fig. 1B). The significant increase of the spine density was observed between ZT10 and ZT13. The spine density moderately decreased, from ZT13 to ZT19, but was still higher than at ZT10. The similar tendency was observed in its CORT level, higher in the awake state (ZT12–ZT22) and lower in the sleep state (ZT1–ZT10) (Higo *et al.* 2011; Supplementary Fig. S3, see section on supplementary data given at the end of this article).

Spine head diameter analysis The morphological changes in spine head diameter were assessed. We classified the spines into three categories using their head diameter: 0.2–0.4 μm as small-head spines, 0.4–0.5 μm as middle-head spines, and larger than 0.5 μm as large-head spines. Upon waking at ZT13, the density of large-head spines was considerably increased from 0.77 spines/ μm (at ZT10) to 1.05 spines/ μm (Fig. 1C and D). The spine density for small- and middle-head spines was not significantly altered.

Depletion of circulating CORT suppressed the change of the spine density

To clarify the effect of CORT on the observed diurnal change of the spine density, ADX was performed, depleting circulating CORT. In addition, metyrapone (a specific inhibitor of CORT synthesis by P450(11 β)) was administrated subcutaneously to eliminate the rise of CORT level upon waking.

Total spine density analysis The spine density of ADX rats was examined at ZT4 and ZT13. ADX decreased spine density at ZT13 from 2.49 to 2.09 spines/ μm . ADX prevented the increase of spine density at ZT13, whereas there was no effect at ZT4 (Fig. 2A and B; Supplementary Fig. S4A, see section on supplementary data given at the end of this article). When 1 mg/kg body weight CORT was injected subcutaneously into ADX rats at ZT11, the spine density increased at ZT13, implying that the low spine

density by ADX was rescued by CORT supplementation (Fig. 3A and B).

Metyrapone was administrated subcutaneously at ZT9, 4 h before the decapitation. The treatment of metyrapone prevented the increase of the spine density at ZT13 (2.12 spines/ μm), resulting in the same level with the sleep state (Fig. 4A and B). Treatment of vehicle (sesame oil) showed no effect (Supplementary Fig. S4A). These results support that the increase of the spine density during the awake state is induced by the elevation of CORT released from the adrenal gland.

Spine head diameter analysis By ADX, the increase of the large-head spine density at ZT13 was suppressed, resulting in the same spine density for all the three subpopulations as those in intact rats at ZT4. In addition, ADX did not affect the spine density for all three subpopulations at ZT4 (Fig. 2C and D). CORT injection into ADX rats rescued the decrease of large-head spine density, resulting in the same spine density for all three subpopulations as those in intact rats at ZT13 (Fig. 3C and D).

The treatment of metyrapone prevented the increase of both the middle- and large-head spine density at ZT13. In the control experiment, sesame oil had no effect on all three subpopulations of the spine density (Fig. 4C and D), implying that the stress from the injection procedure had no effect.

Determination of CORT levels in the hippocampus after the injection of CORT

The concentration of CORT in the ADX rats at 2 h after the CORT injection was determined by the MS analysis. Chromatographic profiles for the fragmented ions of CORT ($m/z=121$) showed a single peak with its retention time of 2.83 min (Supplementary Fig. S5A and B, see section on supplementary data given at the end of this article). The average concentration of CORT in the hippocampus was 23.7 ng/g wet weight (68.4 nM; $n=3$), slightly higher than that in the CSF of intact rats in the awake state (~ 30 nM). Upon CORT injection into ADX rats, the hippocampal CORT became much higher than that in ADX rats without CORT injection (6.9 nM; Higo *et al.* 2011).

Low level CORT rapidly increased spine density in isolated hippocampal slices

Since the spine density in the *in vivo* hippocampus changed within 3 h, we investigated the molecular mechanism of this rapid spine change by using isolated hippocampal slices. Since the physiological level of CORT

Figure 2

Effect of adrenalectomy (ADX) on the diurnal change of the spine density. Endogenous CORT was depleted by ADX, and spine density was analyzed at ZT4 (ZT4_ADX) and ZT13 (ZT13_ADX). (A) Representative images of confocal micrographs; the spines along the dendrite of ADX rats at ZT13. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μm. (B) Effect of ADX on the total spine density. Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as mean ± s.e.m. (C) Histogram of spine head diameters at ZT4 (closed white

circle) and ZT13 (closed black circle) and of ADX rats at ZT4 (closed red circle) and ZT13 (closed blue circle). (D) Density of three subtypes of spines at ZT4 (white column) and ZT13 (black column) and in ADX rats at ZT4 (red column) and ZT13 (blue column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean ± s.e.m. The statistical significance yielded: $^{**}P < 0.01$ and $^{*}P < 0.05$. For each condition, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~6000–8000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

at ZT13 in CSF is ~30 nM (Higo *et al.* 2011), we investigated the effect by the application of 30 nM CORT on the dendritic spine density in hippocampal acute slices.

Total spine density analysis Following a 1-h treatment with 30 nM CORT on isolated hippocampal slices, treated dendrites had more spines (1.40 spines/μm) than control dendrites (1.16 spines/μm) (Fig. 5A and B). It should be noted that the CORT level in control slices was ~2 nM (Hojo *et al.* 2011, Ooishi *et al.* 2012). In the control condition, the spine density did not decline, even after 5 h (Supplementary Fig. S6, see section on supplementary data given at the end of this article), indicating the slices were sufficiently alive.

Blocking GR by 10 μM RU486 completely abolished the CORT-induced spinogenesis (1.14 spines/μm; Fig. 6A and B; Supplementary Fig. S4B). Although GR is known as a nuclear translocation receptor, the inhibition of gene transcriptions by 4 μM actinomycin D had no effect on the

CORT-induced spinogenesis (1.40 spines/μm). CHX, an inhibitor of protein synthesis, completely abolished the CORT-induced spinogenesis (1.14 spines/μm) at 20 μM (Fig. 6C and Supplementary Fig. S4B). These results suggest that the observed CORT-induced spinogenesis is elicited by synaptic GR (Ooishi *et al.* 2012), which can trigger signaling cascades rapidly (~1 h). It should be noted that these blockers and inhibitors alone did not significantly affect the spine density within experimental error (Supplementary Fig. S7A and B, see section on supplementary data given at the end of this article), indicating that the observed inhibitory effects are not simply due to the blocker's nonspecific suppressive effects. Blocking mineralocorticoid receptors (MR) by 10 μM spironolactone did not affect the spine density (1.35 spines/μm).

Spine head diameter analysis Upon treatment with 30 nM CORT in 1 h, both the small- and middle-head spines increased significantly (Fig. 5C and D).

Figure 3

Effect of the administration of CORT on ADX rats. Exogenous CORT was administered subcutaneously (1 mg/kg body weight) on ADX rats at ZT11. Spine density was analyzed at ZT13 (ZT13_ADX+CORT). (A) Representative images of confocal micrographs; the spines along the dendrite of ADX rats with CORT administration. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μm . (B) Effect of the administration of CORT on the total spine density. Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as mean $\pm$ S.E.M. (C) Histogram of spine head diameters at ZT4 (closed white circle) and ZT13 (closed black

circle), in ADX rats at ZT13 (closed blue circle), and in CORT-administered ADX rats (closed green circle). (D) Density of three subtypes of spines at ZT4 (white column) and ZT13 (black column), in ADX rats at ZT13 (blue column), and in CORT-administered ADX rats (green column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean $\pm$ S.E.M. The statistical significance yielded: $^{**}P < 0.01$, $^{*}P < 0.05$ vs 'ZT13' and 'ZT13_ADX'. For each condition, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~6000–8000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

The density of large-head spines was not significantly altered. Blocking GR abolished the effect of CORT by decreasing the density of middle-head spines (Supplementary Fig. S8A, see section on supplementary data given at the end of this article).

Inhibition of kinases suppressed CORT-induced spinogenesis

To identify the kinases that are included within the downstream of GR signaling, the CORT-induced spinogenesis with co-treatments of specific inhibitors for kinases was investigated.

Total spine density analysis Application of 10 μM H-89 (PKA inhibitor), 10 μM chelerythrine (PKC inhibitor), 25 μM U0126 (ERK inhibitor), and 10 μM LIMK inhibitor prevented the effect of 30 nM CORT (Fig. 7A and B; Supplementary Fig. S4B). On the other hand, the

application of 10 μM SP600125 (JNK inhibitor) did not alter the effect of CORT. These results indicate that 30 nM CORT promoted the spinogenesis via PKA, PKC, ERK MAPK, and LIMK signaling pathways. Since the concentrations of inhibitors applied are at their recommended levels (Birnbbaum *et al.* 2004, Venugopal *et al.* 2007, Hammond *et al.* 2008, Benakanakere *et al.* 2010, Scott *et al.* 2010), the observed inhibitory effects are not artifacts due to the excess amount of inhibitors. These kinase inhibitors alone did not significantly affect the spine density (Supplementary Fig. S7C).

Spine head diameter analysis Inhibiting PKA, ERK, and LIMK abolished the effect of CORT, decreasing the density of small-head spines (Fig. 7C and D). Inhibiting PKC decreased the density of middle-head spines. On the other hand, inhibiting JNK had no effect on each class of the spine density, implying that these effects of kinase inhibitors were not nonspecific.

Figure 4

Effect from the inhibition of CORT synthesis on the diurnal change of the spine density. The synthesis of CORT at the adrenal gland was inhibited by metyrapone. Vehicle (sesame oil (ZT13 + sesame)) or 50 mg/kg body weight metyrapone was administered subcutaneously at ZT9 and spine density was analyzed at ZT13 (ZT13 + metyra). (A) Representative images of confocal micrographs; the spines along dendrite of metyrapone administered group. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μm. (B) Effect of metyrapone on the total spine density. Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as mean ± s.e.m. (C) Histogram of spine head diameters at ZT4 (closed white

circle) and ZT13 (closed black circle), in metyrapone administered group (closed red circle), and in vehicle administered group (closed blue circle). (D) Density of three subtypes of spines at ZT4 (white column) and ZT13 (black column), in metyrapone administered group (red column), and in vehicle administered group (blue column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean ± s.e.m. The statistical significance yielded: ** $P < 0.01$ vs 'ZT13'. For each condition, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~6000–8000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

Discussion

The current study showed that the spine density of CA1 pyramidal neurons in the hippocampus changed along the circadian cycles of the CORT level. The moderately rapid increase of the spine density from the sleep state to the awake state is probably induced by the rise in CORT level. Such a moderately rapid spine increase might be induced by kinase signaling, including PKA PKC, ERK MAPK, and LIMK.

Diurnal change of spine density in the hippocampus and cortex

The observed increase in spine density (~20%) in the hippocampus could facilitate memory performance (Leuner & Shors 2004, Luine & Frankfurt 2012), and the spine increase may have a correlation with the diurnal change of the hippocampal-dependent memory performance (Ruby *et al.* 2008).

The change of the spine density along the sleep–wake cycle is also observed in the cortex, including infralimbic cortex layer III (Perez-Cruz *et al.* 2009), sensorimotor cortex layer V (Maret *et al.* 2011), barrel cortex layer V (Yang & Gan 2012), and primary cerebral cortex layer II/III (Hayashi *et al.* 2013). In these studies, the spine density increases also in the awake state and decreases in the sleep state, probably resulting in the diurnal change of the cortex-dependent memory performance (Liston *et al.* 2013). However, the detailed mechanisms are not clarified.

By ADX and the s.c. administration of metyrapone, we demonstrated that the rise in CORT level upon waking increased spine density in the hippocampus. Perez-Cruz *et al.* (2009) show that the chronic restraint stress diminishes the wake-induced increase of the spine density in the cortex. These results imply that the increase of spines in the cortex might also be due to the change in

Figure 5

Time dependency of CORT effects on the spine density in isolated hippocampal slices. Spines in isolated hippocampal slices were analyzed along the secondary dendrites of CA1 pyramidal neurons in the stratum radiatum. 30 nM CORT was treated on acute hippocampal slices for 1 h (CORT_1 h), 2 h (CORT_2 h), and 3 h (CORT_3 h) in ACSF. (A) Representative images of confocal micrographs; the spines along dendrite without drugs (control) and with 30 nM of CORT treatment for 1 h. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μm. (B) Time dependency of CORT effects on the total spine density. As a control, no treatment with CORT for 1 h (control (1 h)) is shown. Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as

CORT level, since the chronic stress is known to diminish the rhythm of the CORT level (Miyazaki *et al.* 2013).

Contribution of slow effects of GR to spine changes may be weak

GR is known as a nuclear translocation receptor, regulating gene transcriptions and protein syntheses. These processes may take 5–6 h, which is slower than the moderately rapid spine increase that appeared within 3 h (from ZT10 to ZT13), for *in vivo* fixed hippocampus (Fig. 1). From DNA microarray analysis, the genes that were regulated by CORT in the hippocampus are investigated comprehensively (Morsink *et al.* 2006). mRNAs of typical synaptic proteins, including NMDA-R, AMPA-R, PSD95, synapsin I, and synaptophysin, were not changed within 5 h, upon CORT treatment. These results suggest that the observed moderately rapid increase (<3 h) in spine

mean $\pm$ S.E.M. (C) Histogram of spine head diameters after a 1 h treatment in ACSF without drugs (closed white circle) and with 30 nM CORT for 1 h (closed black circle), 2 h (closed red circle), and 3 h (closed blue circle). (D) Density of three subtypes of spines after a 1 h treatment in ACSF without drugs (white column) and with 30 nM CORT for 1 h (black column), 2 h (red column), and 3 h (blue column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean $\pm$ S.E.M. The statistical significance yielded: ** $P < 0.01$ and * $P < 0.05$. For each condition, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~3000–4000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

density upon waking may be too rapid to slow genomic effects of GR but might be driven by rapid kinase-driven effects as observed in isolated hippocampal slices.

Rapid spine increase by physiologically low level CORT

CORT-induced rapid spinogenesis via synaptic GR and kinases In isolated hippocampal slices, the application of 30 nM CORT, approximately the same level with that in the CSF during the awake state (Higo *et al.* 2011), increased the spine density within 1 h, from the control slices with a CORT level of ~2 nM. The effect of CORT was blocked by RU486, implying that CORT effect was mediated by GR. Since RU486 suppresses not only GR but also progesterone receptor (PR), progesterone (PROG) effect should be considered. The treatment of slices with 10 nM PROG (an approximately equal level in hippocampus (Hojo *et al.* 2009)) for 1 h did not significantly increase the spine

density within experimental error (data not shown), excluding the involvement of PROG and PR in the observed spinogenesis.

GR has been observed to localize within the postsynaptic structures with postembedding immunogold staining (Komatsuzaki *et al.* 2012, Ooishi *et al.* 2012), and there is increasing evidence that membrane-located GR could rapidly modulate synaptic functions by directly activating protein kinases pathways (Maggio & Segal 2010, Groeneweg *et al.* 2012).

The current CORT-induced spinogenesis required PKA, PKC, ERK, and LIMK. Membrane GR-induced rapid PKA activation (~ 1 h) has been demonstrated in rat the basolateral amygdala and prefrontal cortex (Roosendaal *et al.* 2002, Barsegyan *et al.* 2010), and the relationship between GR activity and PKC also been shown (Liu & Chen 1995, French-Mullen 1995). Both rapid ERK/MAPK activation (~ 15 min) and LIMK activation (~ 20 min) through GR have been demonstrated in the hippocampal slices and cultures of hippocampal neurons (Jafari *et al.* 2012, Liston *et al.* 2013).

Downstream cascade of the kinase networks In hippocampal neurons, there may be a phosphorylation pathway: PKC $\rightarrow$ RhoA $\rightarrow$ ROCK $\rightarrow$ LIMK (Pilpel & Segal 2004, Shi *et al.* 2009). LIMK phosphorylates cofilin, an actin-associated protein, resulting in assembly of actin cytoskeletal matrices (Yang *et al.* 1998, Bernstein & Bamberg 2010, Yuen *et al.* 2011). GR modulation of spine morphology via LIMK and the cofilin dependent pathway is shown in primary cultured hippocampal neurons (Liston *et al.* 2013).

In the CA1 region, ERK cascade is known to couple with PKA and PKC via PKA $\rightarrow$ B-Raf $\rightarrow$ ERK, PKC $\rightarrow$ Raf1 $\rightarrow$ ERK in synaptic modulation (Roberson *et al.* 1999). One of the targets of ERK in spine reorganization might be cortactin, since ERK is known to phosphorylate cortactin, an actin-associated protein (Martinez-Quiles *et al.* 2004). Phosphorylated cortactin promotes actin fiber remodeling working with actin-related protein 2/3 complex

Figure 6

Effects by the blockade of receptors and inhibition of gene expressions on CORT-induced spinogenesis. (A) Representative images of confocal micrographs; the spines along dendrite with 30 nM CORT and 10 μM RU486 (blocker of glucocorticoid receptor (GR)) (CORT + RU) for 1 h. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso) and three-dimensional model illustrations (model) are shown together. Bar, 5 μm. (B) Effects from the blocker of GR and mineralocorticoid receptor (MR) on the CORT-induced spinogenesis. A 1 h treatment in ACSF without drugs (control), with 30 nM CORT, with 30 nM CORT and 10 μM RU486 (CORT + RU), and with 30 nM CORT and 10 μM spironolactone (blocker of MR) (CORT + Spiro). Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as mean $\pm$ S.E.M. (C) Effects by the inhibition in mRNA and protein synthesis on the CORT-induced spinogenesis. A 1 h treatment in ACSF without drugs (control), with 30 nM CORT, with 30 nM CORT and 4 μM actinomycin D (translation inhibitor) (CORT + ActD), and with 30 nM CORT and 20 μM cycloheximide (transcription inhibitor) (CORT + CHX). Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as mean $\pm$ S.E.M. The statistical significance yielded: $**P < 0.01$ vs 'CORT'. For each drug treatment, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~ 3000 –4000 spines. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

Figure 7

Suppression effects by kinase inhibitors on CORT-induced spinogenesis. Kinase inhibitors were co-treated with 30 nM CORT on isolated hippocampal slices. A 1 h treatment in ACSF without drugs (control), with 30 nM CORT (CORT), with 30 nM CORT and 10 μM H89 (PKA inhibitor) (CORT+H89), with 30 nM CORT and 10 μM chelerythrine (PKC inhibitor) (CORT+Chel), with 30 nM CORT and 25 μM U0126 (ERK inhibitor) (CORT+U), with 30 nM CORT and 10 μM LIMK inhibitor (CORT+LIMKi), and with 30 nM CORT and 10 μM SP600125 (JNK inhibitor) (CORT+SP). (A) Representative images of confocal micrographs; the spines along dendrite with CORT and H89, with CORT and chelerythrine, with CORT and U0126, with CORT and LIMK inhibitor. Maximal intensity projections onto XY plane from z-series confocal micrographs (MAX-XY), images analyzed by Spiso-3D (Spiso), and three-dimensional model illustrations (model) are shown together. Bar, 5 μm . (B) Effects by the co-treatment of kinase inhibitors on the total spine density. Vertical axis represents the average number of spines per 1 μm of dendrite. Data are represented as

mean $\pm$ S.E.M. (C) Histogram of spine head diameters after a 1 h treatment in ACSF without drugs (closed white circle), with CORT (closed black circle), with CORT and H89 (closed red circle), with CORT and chelerythrine (closed blue circle), with CORT and U0126 (closed green circle), with CORT and LIMK inhibitor (closed orange circle), and with CORT and SP600125 (closed purple circle). (D) Density of three subtypes of spines after a 1 h treatment in ACSF without drugs (white column), with CORT (black column), with CORT and H89 (red column), with CORT and chelerythrine (blue column), with CORT and U0126 (green column), with CORT and LIMK inhibitor (orange column), and with CORT and SP600125 (purple column). From left to right, small-head spines (small), middle-head spines (middle), and large-head spines (large) type. Data are represented as mean $\pm$ S.E.M. The statistical significance yielded: ** $P < 0.01$, * $P < 0.05$ vs 'CORT'. For each drug treatment, we investigated three to four rats, six to eight slices, 30–40 neurons, 60–80 dendrites, and ~ 3000 –4000 spines. (Weaver *et al.* 2001), as well as scaffold protein Shank in the PSD at the SH3 domain (Daly 2004).

Taken together, we can propose the schematic illustration of the CORT signaling pathway as shown in Fig. 8. Through this pathway, the rise in the CORT level upon waking may increase the spine density in the hippocampus.

Comparison between *in vivo* hippocampus and in isolated hippocampal slices

Diurnal change of CORT level in the *in vivo* hippocampus

Circulating CORT level changes along the circadian

rhythm (Migeon *et al.* 1956, Moore & Eichler 1972). The diurnal change of the CORT level in the hippocampus has also been shown by using the microdialysis in combination with RIA (Linthorst & Reul 2008, Qian *et al.* 2012). These studies, however, did not show the absolute CORT concentration in the hippocampus. On the other hand, our previous study showed the diurnal change of the CORT level in the CSF: ~ 30 nM in the awake state and ~ 3 nM in the sleep state (Higo *et al.* 2011; Supplementary Fig. S3). The concentration was determined with LC-MS/MS quantitatively. Therefore, we applied 30 nM CORT to investigate the effect from the rise in CORT upon waking.

Figure 8

Schematic illustration of CORT-driven multiple kinase pathways. Upon binding of CORT, GR induces the sequential activation of PKA, PKC, ERK MAPK, and LIMK. LIMK phosphorylates cofilin, resulting in actin reorganization and subsequent spinogenesis, whereas ERK/MAPK phosphorylates cortactin. A full colour version of this figure is available at <http://dx.doi.org/10.1530/JOE-15-0078>.

Two hours after the s.c. injection of 1 mg/kg body weight CORT on ADX rats, the level of CORT increased to ~70 nM, which induced the increase of the spine density, especially large-head spine density. It was also demonstrated that after the s.c. injection of 1 mg/kg body weight CORT, the CORT level was elevated for 15–120 min in the hippocampus (Droste *et al.* 2008).

Conditions in isolated hippocampal slices The isolated hippocampal slices, used for the spine analysis, have very low CORT because CORT was leaked to the ACSF during

the incubation. The CORT level was ~2 nM, which was determined by the MS analysis (Hojo *et al.* 2011, Komatsuzaki *et al.* 2012, Ooishi *et al.* 2012). Following an exposure to anesthesia and the sacrifice of rats, a high-dose of CORT (~1 µM) is secreted from the adrenal cortex and readily reaches the brain. Therefore, the CORT concentration in the freshly isolated hippocampus was 150–500 nM (Komatsuzaki *et al.* 2012). Incubation for 2 h is enough to wash out such a high level of CORT from hippocampal slices (Supplementary Fig. S1). For these reasons, the current spinogenesis occurred upon the increase in the CORT level from ~2 nM (control) to 30 nM. We have found that even 10 nM CORT is enough to increase the spine density (Supplementary Fig. S9, see section on supplementary data given at the end of this article; Higo *et al.* 2011).

The spine density of isolated hippocampal slices (Figs 5, 6 and 7) is significantly lower than the spine density of *in vivo* fixed hippocampus (Figs 1, 2, 3 and 4). This may be due to the slicing with ice-cold water. Spines are known to disappear transiently when the cooled hippocampus is sliced (Kirov *et al.* 2004). Through recovery incubation of the slices for 2 h at room temperature, the spine density may increase to some extent. Perfusion fixation of the hippocampus *in vivo* was performed at body temperature (~37 °C), much warmer than the fixation temperature of isolated hippocampal slices, preserving more spines.

Concentration-dependent functions of non-stress level of CORT in the hippocampus

The rapid functions of low level CORT have been reported in several studies. In hippocampal CA1 pyramidal neurons, 100 nM of CORT facilitates the long-term potentiation induced by high-frequency stimulation (Wiegert *et al.* 2006), and 10–100 nM of CORT rapidly enhances the mEPSC frequency concentration dependently (Karst *et al.* 2005). This enhancement was via MR, whereas 30 nM CORT-induced spinogenesis in the current study was not via MR but via GR. Since the affinity of GR for CORT is sufficiently high (dissociation constant K_d , 2.5–5 nM; Reul & de Kloet 1985), GR is activated significantly by 30 nM CORT.

An inverted U-shape effect of CORT, including the amplitude of the population spike, is known to be weakened with the increase of CORT concentration above a certain threshold (~50 nM), whereas this effect is enhanced with the increase of CORT below the threshold (Diamond *et al.* 1992). Our earlier and current

study showed that the CORT effect on spine density also had a U-shape relationship; 200–1000 nM CORT increased the spine density, 100 nM CORT had no effect (threshold; Komatsuzaki *et al.* 2012), and 10–30 nM CORT increased the spine density (Higo *et al.* 2011, current study).

Physiological importance of the circadian rhythms of spine and CORT

Several studies have shown that memory performance depends on circadian rhythm (Eckel-Mahan & Storm 2009). The score of the novel recognition task, the hippocampal-dependent memory test, shows diurnal change, higher in the awake state than in the sleep state (Ruby *et al.* 2008). In this study, the rhythm for memory performance is abolished by the disruption of the circadian system, most likely resulting in the disruption of CORT rhythm. The score of the rotarod motor learning task, which is dependent on motor cortex, is higher when training occurs during the circadian CORT peak than during the trough (Liston *et al.* 2013). The disruption of the CORT rhythm by the administration of CORT diminished the newly formed spines following motor training, resulting in impaired memory performance. This indicates that the rhythm of CORT not only increases spines but also supports the survival of newly formed spines. Other studies showed that the spatial memory (which is hippocampal dependent) and working memory (which is prefrontal cortex dependent) were impaired by ADX (Conrad *et al.* 1997, Mizoguchi *et al.* 2004). Furthermore, ADX rats show depression-like behavior in the rotarod test (Mizoguchi *et al.* 2008). Such memory and cognitive impairments are rescued by the regeneration of CORT rhythm by the combination of implant of the CORT pellet and oral CORT treatment, only during the awake phase. Even in humans, the retrieval of emotional and neutral texts is impaired by the suppression of the morning rise in cortisol (Rimmele *et al.* 2010). The current results are useful to explain the mechanisms of these diurnal changes of memory performance.
