Abstract

Hyperglucagonemia, a hallmark in obesity and insulin resistance promotes hepatic glucose output, exacerbating hyperglycemia and thus predisposing to the development type 2 diabetes. As such, glucagon signaling is a key target for new therapeutics to manage insulin resistance. We evaluated glucagon homeostasis in lean and obese mice and people. In lean mice, fasting for 24 h caused a rise in glucagon. In contrast, a decrease in serum glucagon compared to baseline was observed in diet-induced obese mice between 8 and 24 h of fasting. Fasting decreased serum insulin in both lean and obese mice. Accordingly, the glucagon:insulin ratio was unaffected by fasting in obese mice but increased in lean mice. Re-feeding (2 h) restored hyperglucagonemia in obese mice. Pancreatic perfusion studies confirm that fasting (16 h) decreases pancreatic glucagon secretion in obese mice. Consistent with our findings in the mouse, a mixed meal increased serum glucagon and insulin concentrations in obese humans, both of which decreased with time after a meal. Consequently, fasting and re-feeding less robustly affected glucagon:insulin ratios in obese compared to lean participants. The glucoregulatory disturbance in obesity may be driven by inappropriate regulation of glucagon by fasting and a static glucagon:insulin ratio.

Introduction

Obesity-associated insulin resistance (IR) is characterized by both hyperinsulinemia and hyperglucagonemia and is a key risk factor for the development of type 2 diabetes (T2DM). Although abnormalities in insulin action have been a major focus of metabolic research in obesity, glucagon is also an important regulator of glycemic control. In fact, Orci and Unger's 'bihormonal hypothesis' (1975) (Unger & Orci 1975) prompted decades of work that created abundant evidence identifying basal and postprandial hyperglucagonemia as drivers of the hyperglycemia observed in people with T2DM

(Baron *et al.* 1987, Shah *et al.* 2000, Lee *et al.* 2014). Plasma glucagon is elevated in people who are obese and insulin resistant (Baron *et al.* 1987, Shah *et al.* 2000), and meal-induced suppression of glucagon is blunted in people with IR (Muller *et al.* 1970, Unger *et al.* 1972, Larsson & Ahren 2000, Knop *et al.* 2007, Bagger *et al.* 2014). In fact, some studies show that people with IR respond to a meal with an increase in glucagon (Muller *et al.* 1970, Knop *et al.* 2007).

Suppression of glucagon signaling improves glycemic control in people with IR (Kazda *et al.* 2016,

Vajda *et al.* 2017, Kostic *et al.* 2018), in hyperinsulinemic/insulin-resistant mice (Lee *et al.* 2014), and in insulin-deficient type 1 diabetic mice (Lee *et al.* 2011, Rivero-Gutierrez *et al.* 2018). Incretin therapies, such as glucagon-like peptide-1 receptor agonists and dipeptidyl peptidase-4 inhibitors, decrease glucagon secretion and reduce blood glucose in people with IR (Nauck *et al.* 1993, Hare *et al.* 2010). The liver is the main site of glucagon action and plays a critical role in the regulation of hepatic glycogenolysis, gluconeogenesis and fatty acid oxidation. Since glucagon and insulin have opposite hepatic metabolic effects, the relative glucagon to insulin signal provides a better understanding of metabolic regulation than measures of either glucagon or insulin alone (Glinsmann & Mortimore 1968, Mackrell & Sokal 1969). Normally, the glucagon:insulin ratio increases during fasting, leading to a predominant glucagon signal, which increases hepatic intracellular concentrations of the second messenger cyclic adenosine monophosphate (cAMP) and downstream PKA and CREB signaling pathways, increasing hepatic glucose output (Seitz *et al.* 1977, Mutel *et al.* 2011). In turn, re-feeding decreases the glucagon:insulin ratio, resulting in dominant insulin signaling that decreases cAMP via activation of phosphodiesterase and reduces hepatic glucose output (Benelli *et al.* 1986). Insulin also acts in a paracrine fashion at the alpha-cell to decrease glucagon secretion (Maruyama *et al.* 1984, Kawamori *et al.* 2009). Accordingly, identifying the effect of fasting and feeding on glucagon, insulin, and the glucagon:insulin ratio (Unger 1971, Parrilla *et al.* 1974) in obesity is important for understanding the hormonal regulation of hepatic metabolic response and the metabolic alterations associated with IR.

The purpose of the present study was to test the hypothesis that obesity dysregulates the normal hormonal glucoregulatory response to fasting and re-feeding. Accordingly, we evaluated circulating glucagon, insulin, and the glucagon:insulin ratio in healthy lean and insulin-resistant obese mice and in people who were lean and metabolically healthy or obese and insulin-resistant during fed and fasted conditions.

Materials and methods

Animal studies

All studies were conducted in male wildtype C57BL/6J mice bred in-house at UT Southwestern Medical Center. Mice were maintained on a 12-h light/12-h darkness cycle

and housed 3–5 mice per cage at least 1 week prior to the study, at which time animals were individually housed. Mice were housed with sani-chip bedding (7090 Teklad). We conducted studies on lean chow fed mice (2016 Teklad Global 16% Protein Rodent Diet, 12% kcal from fat) and diet-induced obese mice (Bio Serv S 1850, 60% kcal from fat) at 18–20 weeks of age. Studies in diet-induced obese mice were conducted after 12–14 weeks on a high-fat diet. Mice fed the high-fat diet weighing less than 37 g were excluded from the studies. With the exception of fasting studies, mice had *ad libitum* access to food and water. All studies were approved by The University of Texas Southwestern Institutional Animal Care and Use Committee.

Fasting duration studies

To achieve fasting durations of 24, 16, 8, or 4 h, fasting was initiated at 10:00h, 18:00h, 02:00h or 06:00h, respectively. Mice were killed at 10:00h by decapitation after open-drop exposure to isoflurane anesthesia. Trunk blood was immediately collected and allowed to clot for 30 min prior to centrifugation at 3000g for 30 min. Serum was collected, aliquoted, and immediately frozen at –80°C.

Fed, fast, re-fed studies

Blood was collected from the tail vein of each mouse at three times over 26 h. Fed blood was collected at 10:00h in mice with *ad libitum* food access. Food was removed at 18:00h and at 10:00h the following day we collected blood from 16 h fasted mice. Immediately following blood collection at 10:00h, mice were offered chow or high-fat diet for 2 h prior to a final blood collection.

Glucagon and somatostatin secretion in perfused mouse pancreas

To directly measure the effect of insulin on glucagon and somatostatin secretion, mouse pancreata were perfused as previously described (Wargent 2009). After an equilibrium period of 15 min at 5.5 mM glucose, the perfusion solution was switched to 2 mM glucose and the concentration of insulin was gradually increased from 0 (0–15 min) to mimic concentrations seen in a lean fasted mouse (8.605 pM; 15–25 min), lean-fed mouse (51.63 pM; 25–35 min), obese hyperinsulinemic mouse (860.5 pM; 35–45 min), and a supraphysiological concentration (8605 pM; 45–55 min). Perfusate was collected continuously with samples pooled at 5-min intervals before being frozen at –80°C until further analysis.

Human studies

Subjects

Twenty-six men and women who were lean and metabolically healthy ($n=9$, five women, 36.3 ± 9.2 years) or obese and metabolically unhealthy ($n=17$, 12 women, 44.0 ± 8.0 years) participated in this study, which was approved by the Human Research Protection Office at Washington University School of Medicine in St. Louis, MO (ClinicalTrials.gov number NCT02706262). Written, informed consent was obtained from all subjects before their participation. All subjects completed a comprehensive medical evaluation at screening, including a history and physical examination, standard blood tests, hemoglobin A1C (HbA1c), an oral glucose tolerance test (OGTT) and magnetic resonance imaging (MRI) (3-T MAGNETOM Vida; Siemens) to determine intrahepatic triglyceride (IHTG) content. The inclusion criteria for the metabolically healthy lean group were BMI 18.5–24.9 kg/m²; IHTG content $\leq 5\%$, serum triglyceride <150 mg/dL, fasting plasma glucose <100 mg/dL, 2-h OGTT plasma glucose ≤ 140 mg/dL, and HbA1c ≤ 5.6 . The inclusion criteria for the metabolically unhealthy obese group were BMI 30–49.9 kg/m²; IHTG content $>5.6\%$ and HbA1c $\geq 5.7\%$ or fasting plasma glucose ≥ 100 mg/dL or 2-h OGTT plasma glucose ≥ 140 mg/dL. No subject had a history of diabetes, took medications known to affect the study outcomes, or consumed excessive amounts of alcohol (>21 units of alcohol/week for men and >14 units for women).

Mixed meal response

Subjects were instructed to avoid caffeine and alcohol for at least 24 h and abstain from exercise 3 days prior to admission to the Clinical and Translational Research Unit (CTRU) at Washington University School of Medicine. Subjects were admitted to the CTRU at 18:00 h the day before the mixed meal study and consumed a standard dinner at 19:00 h. At 06:30 h the following morning, after subjects fasted for 11 h overnight, a catheter was inserted into an antecubital vein for serial blood sampling. At 07:00 h a standard meal, containing one-third of estimated daily energy requirements (Mifflin *et al.* 1990) and 50% of energy as carbohydrate, 35% as fat, and 15% as protein, was provided and ingested over 30 min. Blood samples were obtained immediately before and 0.5, 1, 1.5, 2, 3, 4, 5 and 6 h after initiating meal ingestion.

Sample analysis

Serum, perfusate, and plasma assays

Serum (mouse), pancreatic perfusate, and plasma (human) glucagon were analyzed by enzyme-linked immunosorbent

assay (ELISA; Cat. # 10-1271-01, Mercodia, Uppsala, Sweden). Serum glucose from mouse studies was analyzed by colorimetric assay (Cat. # G7519, Pointe Scientific Inc., Canton, MI, USA). Serum insulin from mouse studies was analyzed by ELISA (Cat. # 80-INSMSU-E10, Alpco). Perfusate somatostatin concentration was measured by ELISA (Cat. # EK-060-03, Phoenix Pharmaceuticals, Burlingame, CA, USA). Plasma glucose in human samples was determined by using an automated glucose analyzer (Yellow Spring Instruments Co, Yellow Springs, OH, USA). Plasma insulin in human samples was measured by using electrochemiluminescence technology (Elecsys 2010, Roche Diagnostics).

Liver analyses

Prior to all analyses, whole mouse livers frozen at -80°C were powdered with a liquid nitrogen cooled mortar and pestle to ensure a homogenous sample.

To determine hepatic cAMP content, an aliquot of powdered liver was weighed and immediately sonicated in a known volume of 0.1 M HCl. The homogenate was then centrifuged at 5000g. The supernatant was removed and assayed for cAMP by enzyme-linked immunosorbent assay (ELISA; Cat # ADI-900-066, Enzo Life Sciences, Farmingdale, NY, USA) and expressed per gram of tissue.

We analyzed liver glycogen content using a previously described colorimetric assay (Lo *et al.* 1970). Briefly, 10–15 mg powdered liver was weighed before being boiled in 30% KOH saturated with Na_2SO_4 for 30 min while shaking. Glycogen was then precipitated with 95% ethanol and pelleted by centrifugation at 3000g for 30 min. The supernatants were aspirated and glycogen pellets were dissolved in distilled H_2O . Phenol (5%) was added to the samples followed by a rapid stream of H_2SO_4 . Samples were then incubated at 30°C for 20 min and absorbance was read at 490 nm. Glycogen content was expressed per gram of tissue.

We isolated RNA from powdered liver samples using TRIzol™ Reagent (Thermo Fisher Scientific). Phenol was eliminated using the water saturated butanol and ether method of Krebs *et al.* (2009). Reverse transcription was performed using Verso cDNA synthesis kit (Thermo Scientific, Inc.), and qPCR performed using PowerUp™ SYBR™ Green Master Mix on the Applied Biosystems QuantStudio 6 Flex Real-Time PCR System (Applied Biosystems™). We used LinReg PCR analysis software to determine the efficiency of amplification from raw CT data (Ramakers *et al.* 2003). ACTβ served as the reference gene for calculating fold change in gene expression using the efficiency- $\Delta\Delta\text{Ct}$ method (Livak & Schmittgen 2001).

Table 1 List of primer sequences for RT-PCR.

Gene	Forward primer (5'–3')	Reverse primer (5'–3')	Gene ID
Mouse <i>Actb</i>	TCGGTGACATCAAAGAGAAG	GATGCCACAGGATTCCATA	11461
Mouse <i>G6pc</i>	CGACTCGCTATCTCCAAGTGA	GTTGAACCACTCTCCGACCA	14377
Mouse <i>Pepck</i>	CTGCATAACGGTCTGGACTTC	CAGCAACTGCCCCGTAATCC	18534
Mouse <i>Cpt1a</i>	CTCCGCCTGAGCCATGAAG	CACCACTGATGATGCCATTCT	12894
Mouse <i>Tat</i>	TGCTGGATGTTGCGTCAATA	CGGCTTCACCTTCATGTTGTC	234724

Mouse primer sequences for real-time PCR are presented in Table 1.

We analyzed hepatic protein expression of phosphorylated and total cyclic AMP response element-binding protein (CREB), phosphorylated activating transcription factor-1 (ATF-1), and phosphorylated and total AKT by Western blot. To prepare lysates, we ground the livers using a liquid nitrogen cooled mortar and pestle, then homogenized the ground liver in RIPA buffer (Santa Cruz Biotechnology) with protease and phosphatase inhibitors (Thermo Scientific). Total protein was quantified via BCA protein assay (Thermo Scientific). Forty micrograms protein per sample were loaded and separated on a 4–12% Bis Tris gel (Invitrogen) and transferred onto a nitrocellulose membrane (0.2 µm pore size). Membranes were blocked for 1 h at room temperature in a blocking solution (Tris-buffered saline with 0.5% Tween 20 (TBST) with 5% w/v nonfat dry milk), and then incubated overnight at 4°C with primary antibodies diluted 1:1000 in blocking solution. The following day, membranes were washed three times for 5 min with TBST, then incubated with a secondary antibody (anti-rabbit IgG, HRP-linked antibody, Cell Signaling #7074) diluted 1:2000 in blocking solution for 1 h at room temperature. Signals were visualized using enhanced chemiluminescence reagents (Invitrogen) on the ChemiDoc imaging system (Bio-Rad) and band intensities were quantified using Image Lab software version 6.0.1 (Bio-Rad). Phosphorylated and total protein content were expressed relative to the within-gel loading control protein, Histone H3. All antibodies were

purchased from Cell Signaling and have been previously verified with appropriate controls (Jewell *et al.* 2019, Townsend *et al.* 2019). We detected total CREB with anti-CREB antibody (# 9197) and phosphorylated CREB levels with anti-phospho-CREB antibody which detects CREB phosphorylated at serine 133 and the phosphorylated form of the CREB-related protein, cyclic AMP-dependent transcription factor ATF-1 (# 9198). We detected total AKT, phosphorylated AKT (Ser473) levels, and Histone H3 with antibody numbers 9272, 9271, and 12648 respectively (Cell Signaling).

Statistical analyses

Statistical analyses were performed in SAS Enterprise Guide 7.1 (SAS Institute Inc.). To assess the effect of fasting duration (0, 4, 8, 16 and 24 h) within diet group (lean and obese) on all dependent variables in our animal studies, we used the mixed model procedure. When statistically significant interactions were found, Tukey's adjustment for multiple comparisons was used to identify significant mean differences. Independent Student's *t*-test assessed differences between lean and obese groups within each timepoint. Data from fasting-re-feeding studies and perfusion studies were analyzed using repeated-measures ANOVA including timepoint and group in the analyses and difference between means assessed by *post hoc* analysis using the Tukey–Kramer correction for multiple comparisons. Pearson's correlations assessed the strength of associations between hepatic cAMP levels and serum glucagon or insulin. Student's *t*-test was used to compare basic characteristics of participants between groups. Two-way ANOVA with time (before and 0.5, 1, 1.5, 2, 3, 4, 5 and 6 after mixed meal ingestion) as the within-subject factor and group (lean and obese) as between-subject factor was used to evaluate the effect of mixed meal ingestion on plasma glucose, insulin and glucagon concentration. When statistically significant interactions were found, Tukey–Kramer's *post hoc* procedure was used to identify significant mean differences. Independent variables were identified as classification variables in all models. Raw data were plotted in Graphpad PRISM®, version 8 for

Table 2 Characteristics of the study participants.

	Lean (<i>n</i> = 9)	Obese (<i>n</i> = 17)
BMI	23.0 ± 1.7 ^a	39.8 ± 5.2 ^b

Results

Glucoregulatory hormone status

In the fed state, diet-induced obese mice were hyperglucagonemic compared to lean mice ($P < 0.05$; Fig. 1A). In lean mice, a 24-h fast increased serum glucagon significantly ($P < 0.05$; Fig. 1A). In contrast, obese mice responded to fasting with a significant decrease in serum glucagon after 8 h of fasting and glucagon remained low after 16 and 24 h of fasting ($P < 0.05$; Fig. 1A). In obese mice, both glucagon and insulin decrease with fasting ($P < 0.05$; Fig. 1A and B). Accordingly, the glucagon:insulin ratio increases with fasting in the lean mouse, but not in obese mice ($P < 0.05$; Fig. 1C). Serum glucose decreases significantly by 16 h of fasting in lean mice. Yet, in line with an insulin-resistant state, the fasting-induced decrease in serum glucose is blunted in obese mice ($P < 0.05$; Fig. 1D). As expected, the glucose:insulin ratio increases with fasting in both groups of mice. However, this ratio is lower in obese mice ($P < 0.05$; Fig. 1E).

Having demonstrated that fasting elicits a decrease in serum glucagon in obese mice, we set out to examine the effects of re-feeding after a 16-h fast. We confirmed that 16 h of fasting significantly decreases both serum glucagon and insulin in the obese mouse ($P < 0.05$; Fig. 2A and B) leading to a non-responsive glucagon:insulin ratio (Fig. 2C). Lean mice responded to the fast with a slight, non-significant, increase in glucagon and decrease in insulin, yielding a significant increase in the glucagon:insulin ratio ($P < 0.05$; Fig. 2A, B and C). Two hours of re-feeding restored the hyperglucagonemic and hyperinsulinemic state in the obese mouse ($P < 0.05$ compared to 16 h fasted), yielding a static glucagon:insulin in obese

mice throughout the study. Interestingly, re-feeding also increased serum glucagon in the lean mice ($P < 0.05$), but to a lesser extent. As expected, serum glucose decreased with fasting and increased with feeding in lean mice, while no significant change was observed after a 16 h fast in the obese group. Re-feeding caused a mild, but significant decrease in serum glucose in obese mice (Fig. 2D).

Downstream targets of glucagon

We next explored if the observed fasting-induced changes in glucagon and the glucagon:insulin ratio affected downstream targets of glucagon signaling. We measured changes in cAMP content in livers from mice in our fasting duration studies (Fig. 3A). In lean mice, hepatic cAMP increased as fasting duration increased to 24 h ($P < 0.05$). In contrast, livers from obese mice show no change in cAMP in response to a fast. Since glucagon and insulin affect cAMP production and breakdown, respectively, we correlated liver cAMP with serum glucagon and insulin (Fig. 4). As expected, in lean mice hepatic cAMP levels correlate positively with serum glucagon ($P = 0.004$, $r = 0.43$) and negatively with serum insulin ($P = 0.006$, $r = -0.42$). Hepatic cAMP does not correlate with glucagon or insulin in diet-induced obese mice, suggesting that hormone-induced changes in hepatic cAMP are dysregulated.

Glucagon-stimulated glycogenolysis is dependent on a rise in cAMP. Thus, we examined liver glycogen content in livers from these mice. In the fed state, liver glycogen did not differ between lean and obese mice. However, obese mice show an attenuation of fasting-induced liver glycogen loss (Fig. 3B). By increasing cAMP, glucagon stimulates the phosphorylation of CREB and the cAMP-regulated enhancer-binding protein, activating transcription factor-1 (ATF-1), which is more responsive to cAMP (Rehfuß *et al.* 1991, Sun *et al.* 1996). In line with our observation that re-feeding in obese mice restores

Figure 1

Serum (A), glucagon, (B) insulin, (C) glucagon:insulin ratio, (D) glucose, and (E) glucose:insulin ratio in lean (fed: $n = 33$ for glucagon and insulin, $n = 14$ for glucose), 4 h: $n = 8$, 8 h: $n = 9$, 16 h: $n = 27$, and 24 h fasted: $n = 8$) and diet-induced obese (fed: $n = 29$, 4 h: $n = 12$, 8 h: $n = 11$, 16 h: $n = 24$, and 24 h fasted: $n = 9$) mice fed *ad libitum*, and fasted for 4, 8, 16, and 24 h. Letters that differ indicate differences within group (a,b,c:Lean, x,y,z:Obese), $P < 0.05$; ****, ***, **, * indicate when obese differs from lean within timepoint, **** $P \leq 0.0001$, *** $P < 0.001$, ** $P < 0.01$, * $P < 0.05$. hyperglucagonemia, 2h of re-feeding after a 16h fast failed to significantly decrease levels of phosphorylated ATF-1 in the livers of obese mice. In contrast, we observed a robust decrease in phosphorylated ATF-1 in the livers of re-fed lean mice ($P < 0.0001$, Fig. 5A and B). Re-feeding, however, did not affect levels of phosphorylated CREB in either lean or obese mice (Fig. 5A and C). Re-feeding after an overnight fast in mice normally stimulates an increase in the phosphorylation of AKT at the liver via downstream insulin signaling (Lu *et al.* 2012). Consistent with a robust rise in insulin with re-feeding, the phosphorylation of hepatic AKT was elevated in both lean and obese mice in response to re-feeding ($P < 0.05$, Fig. 5D and E).

Figure 3

Liver (A) cAMP in lean (fed: $n = 12$, 4 h: $n = 8$, 8 h: $n = 8$, 16 h: $n = 6$, 24 h fasted: $n = 8$) and diet-induced obese (fed: $n = 13$, 4 h: $n = 11$, 8 h: $n = 12$, 16 h: $n = 7$, 24 h fasted: $n = 9$) mice and (B) glycogen in lean (fed: $n = 7$, 4 h: $n = 7$, 8 h: $n = 8$, 16 h: $n = 6$, 24 h fasted: $n = 6$) and diet-induced obese (fed: $n = 7$, 4 h: $n = 11$, 8 h: $n = 10$, 16 h: $n = 6$, 24 h fasted: $n = 7$ mice) mice fed *ad libitum*, or fasted for 4, 8, 16, or 24 h. Letters that differ indicate differences within group (a,b,c,Lean, x,y,z,Obese), $P < 0.05$; **, * indicates when obese differs from lean within timepoint, ** $P < 0.01$, * $P < 0.05$. Figure 4

Pearson's correlation (95% confidence interval) between (A and C) serum glucagon and hepatic cAMP and (B and D) serum insulin and hepatic cAMP in lean ($n = 41$) and diet-induced obese mice ($n = 50$).

Because glucagon regulates the expression of genes involved in gluconeogenesis and fatty acid oxidation by affecting cAMP, we tested the effects of fasting on cAMP target genes in the liver (Zhang *et al.* 2005). In lean mice, fasting significantly increased mRNA expression of phosphoenolpyruvate carboxykinase (*Pepck*), glucose 6-phosphatase (*G6Pc*), tyrosine aminotransferase (*Tat*) and carnitine palmitoyl transferase-1a (*Cpt1a*), with the most robust increase occurring after 16h of fasting (Fig. 6, $P < 0.05$). In contrast, fasting in obese mice had minimal to no effect on gene expression, regardless of fasting duration (Fig. 6).

Pancreatic insulin sensitivity

To establish that the hyperglucagonemia in obesity and the observed decrease in glucagon in the fasted state are due to changes in pancreatic glucagon secretion, we perfused the pancreas of lean and obese mice (fed vs 16-h fasted) with low glucose (2mM) and increasing concentrations of insulin. We observed that, prior to perfusing insulin, decreasing perfusate glucose concentration from 5.5 mM (equilibrium period) to 2 mM increased glucagon secretion in lean, but not obese mice. Obesity increased pancreatic glucagon release relative to that seen in lean mice (Fig. 7A, $P < 0.05$). We further observed that pancreata of fasted obese mice release less glucagon than those of fed obese mice ($P < 0.05$). Incremental increases in perfusate insulin concentration evoked an equally robust decrease in glucagon secretion in all groups of mice (Fig. 7B). Somatostatin release was higher in lean than in obese mice

Figure 5

Phosphorylation levels of (A, B and C) Ser133 in CREB, Ser63 in ATF-1, and total CREB protein, as well as (D and E) phosphorylated Ser473 in AKT and total AKT protein in livers of lean (fasted: $n = 6$, re-fed: $n = 8$) and diet-induced obese (fasted: $n = 6$, re-fed: $n = 6$) mice fasted for 16 h or re-fed for 2 h after a 16 h fast. and fasting of obese mice caused a rise in somatostatin (Fig. 7C). Again, insulin lead to a decrease in somatostatin (Fig. 7D).

Basal and postprandial plasma glucagon and insulin in people who are lean and people with obesity and IR

Having demonstrated that fasting in the obese mouse elicits a decrease in serum glucagon, we set out to examine the effects of fasting and re-feeding in people who were lean and metabolically healthy or obese and metabolically unhealthy (Table 2). Basal plasma glucagon concentration obtained after subjects fasted for 12 h overnight was greater in people who were obese than those who were lean ($P < 0.05$, Fig. 8A). Mixed meal consumption caused a greater increase in plasma glucagon and insulin in the obese than in the lean group (Fig. 8A and B). Basal plasma glucagon:insulin ratio was greater in the lean than the obese group (Fig. 8C). Plasma glucagon:insulin ratio decreased to a similar value in both lean and obese subjects from 30 to 90 min after subjects consumed the mixed meal, and subsequently increased to basal values in both groups. However, the increase in this ratio was more rapid in the lean group (Fig. 8C). Basal plasma glucose concentrations and the postprandial rise in plasma glucose were greater in the obese than lean group ($P < 0.05$, Fig. 8D). As we observed in our mouse model, both the basal and postprandial plasma glucose:insulin ratio was lower in the obese than lean group (Fig. 8E), indicative of impaired insulin sensitivity (Legro *et al.* 1998, Guerrero-Romero & Rodriguez-Moran 2001, Vuguin *et al.* 2001).

Discussion

Here we report that extended fasting in the obese mouse decreases α -cell glucagon secretion. Contrary to the

canonical fasting-induced rise in glucagon, obese mice respond to an extended fast with a robust decrease in serum glucagon. In fact, 8 h of fasting caused a greater decrease in serum glucagon than serum insulin concentrations. Accordingly, while the glucagon:insulin ratio increases with fasting in lean mice, this ratio does not change with fasting in obese mice.

Glucagon was significantly elevated after 24 h of fasting in lean mice. Yet, an 8–24 h fast in obese mice induced a robust decrease in serum glucagon. Singh *et al.* set out to examine the role of somatostatin receptor subtype-2 on glucagon secretion in fed and overnight

Figure 6

Relative mRNA expression of glucagon-responsive genes, (A) phosphoenolpyruvate carboxykinase (*Pepck*), (B) glucose 6-phosphatase (*G6pc*), (C) tyrosine aminotransferase (*Tat*), and (D) carnitine palmitoyl transferase-1a (*Cpt1a*) in lean (fed: $n = 8$, 4 h: $n = 8$, 8 h: $n = 5$, 16 h: $n = 6$, 24 h fasted: $n = 4$) and diet-induced obese (fed: $n = 12$, 4 h: $n = 12$, 8 h: $n = 10$, 16 h: $n = 6$, 24 h fasted: $n = 8$) mice fed *ad libitum* or fasted for 4, 8, 16, or 24 h. Gene expression was normalized to the housekeeping gene ACT β and presented as relative expression compare to the lean-fed group. Letters that differ indicate differences within group (a,b,c,Lean, x,y,z,Obese), $P < 0.01$; ****, ***, **, * indicates when obese differs from lean within timepoint, **** $P \leq 0.0001$, *** $P < 0.001$, ** $P < 0.01$, * $P < 0.05$. Bars indicate means $\pm$ s.e.m.

Figure 7

Pancreatic secretion of (A) glucagon (pmol/L), (B) glucagon (% change from baseline), (C) somatostatin (ng/mL), and (D) somatostatin (% change from baseline) in response to insulin perfusion in lean-fed ($n = 5$), obese fed ($n = 7$), and obese 16 h fasted ($n = 8$) mice. *Differs from fed obese, within timepoint $P < 0.05$. Values are means $\pm$ S.E.M.

fasted lean and diet-induced obese mice. Similar to our studies, they reported that in obese mice fed serum glucagon concentrations were 66% higher than fasted serum glucagon concentrations, while in lean mice glucagon increased with fasting (Singh *et al.* 2007). Unfortunately, their results might have been confounded because of the use of different methods to assess plasma glucagon concentration in the fed and fasted states; they used an ELISA to assess glucagon in fasted samples and an RIA to determine glucagon in fed samples. Lavine *et al.* showed that liver cAMP concentrations decreased with fasting in the ob/ob mouse, but increased in wildtype controls. The authors concluded that the cause of such a paradoxical metabolic response to fasting is unknown

(Lavine *et al.* 1975). Our findings support the possibility that the decline in hepatic cAMP with fasting in the ob/ob mouse model was due to a decreased glucagon stimulation.

Although it is difficult to compare a fast in a human to that of a mouse, a 24-h food deprivation in a mouse may be more appropriately considered a starvation model rather than a fast. In fact, a 5–6 h fast in a mouse may be more comparable to an overnight 12-h fast in humans (Andrikopoulos *et al.* 2008, Ayala *et al.* 2010, Jensen *et al.* 2013). Thus, to examine the effects of extended fasting on glucagon homeostasis in the obese T2DM human, a 72-h fast would likely be required to make comparisons in humans to our long-term fasting data in the mouse. In healthy people, plasma glucagon increases after a 72-h fast (Aguilar-Parada *et al.* 1969, Nair *et al.* 1987, Beer *et al.* 1989, Boyle *et al.* 1989, Hojlund *et al.* 2001), which is equivalent to a 16–24 h fast in mice (Andrikopoulos *et al.* 2008, Ayala *et al.* 2010, Jensen *et al.* 2013). Yet, glucagon does not increase after a 12-h fast in healthy people (Hojlund *et al.* 2001, Nuttall *et al.* 2015), equivalent to a 6-h fast in mice (Andrikopoulos *et al.* 2008, Ayala *et al.* 2010, Jensen *et al.* 2013). Marliiss *et al.* (1970) examined circulating glucagon in seven people with obesity over various intervals of a prolonged fast. Plasma glucagon rose 3 days after initiation of the fast, followed by a gradual return toward basal levels after 5, 14, and 42 days of fasting. The results of this study suggest that, unlike obese mice, obese humans respond to a short-term fast with an increase in circulating glucagon. However, glucagon values on days 1 and 2 of the fast in the study of Marliiss *et al.* were not reported; thus, it is possible that a decline in glucagon during short-term fasting could have been missed. In concert with previous studies (Muller *et al.* 1970, Knop *et al.* 2007), we show that people with obesity do not suppress plasma glucagon in response to a meal.

Figure 8

Plasma concentrations of (A) glucagon, (B) insulin, (C) glucagon: insulin ratio, (D) glucose, and (E) glucose: insulin ratio before (time 0) and for 6 h after ingesting a mixed meal consumed over 30 min in lean ($n = 9$) and obese ($n = 17$) participants. Letters that differ indicate differences within group (^{a,b}Lean, ^{x,y}Obese) in response to the meal, $P < 0.05$; **, * indicates when obese differs from lean within timepoint, ** $P < 0.01$, * $P < 0.05$. Values are means $\pm$ S.E.M.

In fact, we observed a robust increase in glucagon immediately following a mixed meal. Similarly, we show that 2h of re-feeding in the diet-induced obese mouse completely restores fed state hyperglucagonemia after a fasting-induced decrease in glucagon. Varying the macronutrient composition of a meal can lead to differential glucagon responses in both normal-weight people and people with obesity (Muller *et al.* 1970, Knop *et al.* 2007). Here, we have examined the impact of mixed meal feeding on the glucagon response in people with and without obesity. Future studies are needed to investigate the impact of acute and chronic diet macronutrient composition on meal-induced changes in glucagon.

The serum or plasma glucagon:insulin ratio is a better determinant of metabolic regulation than glucagon or insulin alone (Unger 1971, Parrilla *et al.* 1974). Moreover the peripheral glucagon:insulin ratio provides a reliable index of the ratio in the portal vein (Felig *et al.* 1974). Normally the glucagon:insulin ratio increases with fasting and starvation (Unger 1971), leading to an increase in hepatic intracellular concentrations of cAMP and downstream signaling (Seitz *et al.* 1977, Mutel *et al.* 2011). In contrast, re-feeding normally causes a decrease in the glucagon:insulin ratio. The predominant insulin signal decreases cAMP by activating phosphodiesterase (Benelli *et al.* 1986). In opposition, glucagon activates cAMP (Jelinek *et al.* 1993), which activates glycogenolysis and the expression of genes involved in gluconeogenesis and fatty acid β -oxidation (Koo *et al.* 2005, Zhang *et al.* 2005). We show that obesity dysregulates fasting-induced changes in circulating glucagon, the glucagon:insulin ratio, and the downstream effects of glucagon signaling at the liver, including cAMP and the concomitant phosphorylation of ATF-1 (Rehfuß *et al.* 1991, Sun *et al.* 1996), and mRNA expression of cAMP-regulated genes (Zhang *et al.* 2005). The static glucagon:insulin ratio in obesity during fasting may contribute to the impairments in glucose homeostasis observed in obesity. Obese mice do not respond to a fast with changes in cAMP or expression of hepatic genes that regulate gluconeogenesis, which may explain why hepatic gluconeogenesis and glucose output, which is elevated in the fed state in obesity, does not change in response to a fast. In line with this hypothesis, Belfiore *et al.* showed that the glucose 6 phosphatase: glucokinase and fructose-1,6-diphosphatase: phosphofructokinase ratios increase in response to a 48h fast in lean mice, but do not change with fasting in obese, hyperglycemic mice (Belfiore *et al.* 1987).

The mechanism responsible for hyperglucagonemia in obesity and T2DM is not well understood. Insulin normally acts in a paracrine fashion to decrease glucagon

secretion (Maruyama *et al.* 1984, Kawamori *et al.* 2009). Thus, it is possible that obesity-induced α -cell IR (Larsson & Ahren 2000, Knop *et al.* 2007, Bagger *et al.* 2014) contributes to hyperglucagonemia. Our studies in the obese mouse demonstrate that fasting decreases the hyperglucagonemia associated with obesity. Using our pancreatic perfusion model, we established that decreasing perfusate glucose from 5.5 mM (equilibrium period) to 2 mM increased glucagon secretion in lean, but not obese mice. This supports our *in vivo* observation that fasting increases glucagon secretion in lean but not obese mice. We subsequently sought to determine how fasting affected insulin-mediated suppression of α -cell glucagon secretion. Our perfusion experiments showed that the decrease in circulating serum glucagon with fasting occurs in the obese mouse as a direct result of a decrease in pancreatic glucagon secretion, obese mice released more glucagon than lean mice, and that neither obesity nor fasting altered insulin inhibition of glucagon secretion. These experiments suggest that mechanisms other than impairment in α -cell insulin sensing (Unger *et al.* 1972, Ipp 2000) cause the dysregulation in glucagon secretion associated with hyperinsulinemia and IR in obesity.

Somatostatin, secreted by pancreatic δ -cells, also exerts a paracrine inhibitory action on α -cell glucagon secretion (Hauge-Evans *et al.* 2009, Cheng-Xue *et al.* 2013, Elliott *et al.* 2015). Thus, we hypothesized that somatostatin secretion may be differentially affected by fasting in obese mice. Our results demonstrate that pancreatic somatostatin secretion from obese mice fasted for 16h is greater than that of fed obese mice. Moreover, in the fed state, pancreata from lean-fed mice secrete more somatostatin than those of obese mice. These results are consistent with an increased inhibitory signal from somatostatin at the α -cell, which could explain the fast-induced decrease in glucagon observed in obese mice.

Glucagon not only regulates glucose homeostasis, but also energy homeostasis. Glucagon increases energy expenditure in humans (Salem *et al.* 2016), non-human primates, and mice (Elvert *et al.* 2018). In fact, glucagon receptor agonists combined with glucagon-like peptide 1 receptor agonists increase energy expenditure and induce weight loss (Henderson *et al.* 2016, Elvert *et al.* 2018). Thus, fasting-induced decreases in glucagon secretion in people with obesity and the resulting alterations in the glucagon:insulin ratio could impede calorie-restrictive approaches to weight loss. Thus, future studies aimed at understanding the impact of fasting-induced changes in glucagon on energy expenditure in obesity are needed.

Conclusion

Fasting in the diet-induced obese mouse induces a progressive decrease in glucagon secretion. Further, in both obese mice and humans, consuming a meal induces a rise in glucagon. We established that in mice this was a result of altered pancreatic glucagon release. This dysregulation of glucagon in obesity results in a more static glucagon:insulin ratio in obese than in normal-weight humans and mice. Future studies are needed to assess the potential importance of alterations in the circulating glucagon:insulin ratio on metabolic function in people with obesity.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

Preclinical studies were supported by grants from the National Institutes of Health grants K99-AG055649, F32-DK107058 (J H S); R01-DK55758, R01-DK099110 and P01-DK088761-01, JDRF Grant 2SRA2016149QR and an unrestricted grant from the Novo Nordisk Research Foundation (P E S). Clinical studies were supported by National Institutes of Health grants DK56341, DK20579 and RR024992, and grants from Janssen R&D and the Pershing Square Foundation (S K).

Author contribution statement

J H S, P E S, and R H U designed the mouse studies. G H S and S K designed and conducted the human clinical studies. J H S performed animal studies and data analysis. S C performed perfusion studies. J H S, P E S, and S K wrote the manuscript. All authors edited the manuscript and approved the final version. S K and P E S are the guarantors of the study.

Prior presentation

Parts of this study were presented in abstract form at the 78th Scientific Sessions of the American Diabetes Association, Orlando, FL, June 22–26, 2018.
